To the students of a new generation Dr. Benjamin Ward Richardson once gave an introductory lecture, afterward published in revised form, concerning the medical pilgrim's progress. In the medical journey through life there are two paths, like those before Christian. One is broad, easy, tempting, and followed by many average commercial physicians. Herein walk the idlers in medicine, men born with the historical silver spoon; born not to work, or who work perforce, despising meritorious labor, comprehending the luxury of idleness, and failing always to understand the greater luxury of industry. Exercising a petty rule from the cradle, they go through life captious, supercilious, and careless. Then another class walks in the broad road—human aspirants to distinction through the ignoble art of paying an insincere deference to the vanity of equals and superiors. Bits of original investigation can be picked up in this way and elaborated out of all recognition, to say nothing of place and position that go by favor. Then there are strolling journeymen along the broad highway—lazy, drowsy, helpless—who take things as they come and let them go as they go, and "muddle away their incomes in paying their debts." The latter they always have. Often dissolute to start with, they become nonentities at last, dying as if they had never been born.

The narrow path is rendered sacred by the noble army of martyrs that have followed it. Hippocrates walked here. Vesalius, with stout heart and firm step trod this way, and found that it led him to the gibbet, thence to rescue anatomy and make it a science, in spite of the howls of a superstitious community. William Harvey avoided no ascent, however difficult, gaining one at last which threw open to his clear vision a new world. Here strove John Hunter, proving for the first time the history of the intellect, says Dr. Richardson, that genius may be the mere child of industry. Here has every man striven who may be considered a master in physic.

Is the straight and narrow path too difficult for ordinary humanity? Does it require genius, unusual power, herculean strength? An excess of modesty is a bad thing, and like every other excess, a limitation. Cowards grow bold in war, the mind gains by discipline, and the intellect by exercise. Whoever relies upon the simple combination of force, fearlessness, and fact, has within

himself the elements of genius for science. Education alone will never positively supply these things. They are more or less inherent in humanity at large, and education makes them of practical avail.

To prepare for the medical pilgrim's progress it is not enough to elect to walk in the right path. Body and mind must be brought into healthful concord. One general principle, that Dr. Richardson considers a key to a thousand more, is simplicity of life to the verge of abstemiousness, as strength and vigor of intellect are inseparably connected with simplicity of living. Frugality is not meanness, and to attune the soul to the work before it is in no sense selfishness.

To get on, the medical pilgrim must ever bear in mind the silent, constitutional, yet rapid, revolution in the science and art of medicine, as well as in human mind and affairs elsewhere. The real object of medical education, according to Erichsen in his address at King's College, is to train the mind to remain open to the reception of truth throughout life, and to meet the varying emergencies of a professional career. In Rasselas, the excellent Dr. Johnson thus sums up the earthly progress of the real student: "The life that is devoted to knowledge passes silently away and is little diversified by events. To talk in public, to think in solitude, to read and to hear, to inquire and answer inquiries, is the business of a scholar. He wanders about the world without pomp or terror, and is neither known nor valued but by men like himself."

ANOTHER VIEW OF LITHÆMIA.

In the *Journal de Médecine et de Chirurgie Pratiques* for September 25, 1891, there is an article founded on a recent brochure by Dr. Henry Cazalis, of Aix-les-Bains, upon the subject of the hygiene and regimen best suited to the lithæmic constitution. To the question, what lithæmia really is, various views are cited. Bouchard considers its cause a vice of nutrition that renders possible the abnormal manufacture or accumulation of various products, such as organic acids, cholesterin, fat, or sugar. This permanent error in nutritive metamorphosis causes or prepares the way for abnormities that differ greatly in symptomatology, anatomical location, and pathogenic development. Lithæmia, then, is an oligotrophia in the sense that the process of nutrition transforms too little material in a given time; or a bradytrophia, as Landouzy calls it, to indicate that nutritive metamorphoses are slow. Beneke and Bence-Jones incline also to the idea of suboxidation. The author of that admirable aphorism which proclaims a man as old as his arteries, considered lithæmia a congestive diathesis, an opinion Huchard shared, finding in this condition "a tendency to digestive attacks and arteriosclerosis."

Lithæmics present certain features in common, as a defect in general nutrition, insufficient elimination of waste products, either by the skin, intestine, or kidneys, and a consequent general excitability, with a profound lassitude mornings, owing to the fact that rest and night retard the combustion of acids and diminish the alkalinity of the blood. There is also a predisposition to congestive phenomena, to nervous affections, great susceptibility to infectious disease—as acute rheumatism—and extreme sensitiveness to changes of temperature. While Dr. Cazalis recognizes all this, one characteristic of supreme importance furnishes him the starting-point of a new theory concerning lithæmia. This is, the fact that there exists in all lithæmics a special irritability of connective tissue that makes it, in consequence of some inherent imperfection, the line of least resistance in the human body. Hence the frequent inflammatory processes and proliferations of this particular structure. Thus also is explained the tendency to venous dilatation, to hernias, dilatation of the stomach, and to joint affections; in other words, to troubles in fibrous, osseous, and cartilaginous tissues, which are but modifications of connective tissue. Valvular lesions, arteriosclerosis and phlebosclerosis, myopathies, various nervous lesions, and interstitial myocarditis are all abnormities in which connective tissue is primarily attacked. Emphysema is nearly always of gouty origin, due, very possibly, to some congenital malformation in the pulmonary connective-tissue fibres. Tuberculosis is rare among lithæmics. When it does exist its progress is slow and there are frequent recoveries, owing to its sclerotic form in consequence of this constitutional predisposition to irritability and proliferation of connective tissue. In various scleroses, such as the alcoholic and syphilitic, according to this authority, there is usually a lithæmic base. Thus it will be readily perceived, on morphological grounds, how iodide of potassium is such a valuable agent in many cases of lithæmia.

In regard to diet, vegetables and fruit should constitute the larger part of every meal at which meat is eaten, and vegetables should be taken with every course of meat. Fat and sugar, and even the quantity of food itself, must be restricted in the case of uricæmics. Water seems the best drink, especially for the gouty. It has been claimed that water in itself has the power to cure gout, increasing the activity of all the forces of combustion and thus augmenting the excretion of urea. It is a great aid to the elimination of organic waste material and the dissolving of fatty acids that produce gall-stones. Only light wines are to be permitted. Champagne is peculiarly poisonous. The hygiene of the lithæmic state consists, broadly, in the following general directions: Lessen as far as possible the production and absorption of organic poisons that, by irritating connective tissue, the weakest part of the organism, produce various lithæmic diseases. Assist elimination in every way, remembering that the function of organs engaged in this duty is frequently imperfect. Modify as far as possible the lithæmic soil—that is to say, an inherent tendency to irritation, inflammation, and proliferation of connective tissue—by the influence of suitable climate, temperature, and residence, by rational gymnastics and exercise, by hydrotherapy and massage, and the careful study and recognition of temperament, which, according to Laycock, is the mode of vital action peculiar to the individual.

ÆSTHETIC DRESS A FACTOR IN CHILDREN'S DISCOMFORT AND DISEASE.

When Oscar Wilde, at the suggestion of Whistler, the artist, undertook a crusade against the ugliness then prevailing in Philistinia, and preached the gospel of beauty in dress, he did a good thing for England and America.

Soft fabrics, light in weight, and suitable as drapery for the human form divine, took the place of heavier textiles that the essentially refined relegated to house-furnishings alone. Women gradually became ornaments in the landscape instead of animated blots upon it. The decrease in the weight of their robes literally lifted from their shoulders and waists a great burden. But how about hapless childhood? How about the babies?

In the Whistler-Wilde æsthetic movement followed Kate Greenaway, with a series of pictures illustrating child-life of a nature calculated to penetrate the hardest heart. Every dear little maid possessed a large hat and a long gown, such as the household grandmothers wore in the ages known as long ago, and every tiny lad appeared in a long coat all buttoned down before, like classic Old Grimes. To the casual observer the combination was of the kind known as "too sweet for anything." Very soon, babyhood at large erupted into long garments and large hats the instant it could walk. Not very steady on its legs, owing to its extreme youth, babyhood had a bad quarter-hour whenever the wind blew. The skirts of coat or gown wound themselves around the poor little shaky limbs, the hat went up and down on one side, or both, and life lost some of its legitimate joys. But babyhood was not to be thus undone. It grasped the hat firmly with both hands, kept its little head in as good a position as circumstances would allow, turned in its toes and tottered forward. In time, babyhood learned just how not to be jarred or knocked down by the wind—learned the lesson so well that the forward totter became its natural gait, to the destruction of grace, proper breathing, and muscular force. Some of these æsthetic babies are now just on the verge of approaching manhood and womanhood. They cannot breathe, stand, or walk well. They lack grace and firmness of movement. Certain energies were early sapped by a style of costume that transformed natural movements into contortions. The twig was bent and the tree deprived of the freedom that rational oversight can secure. This permanent totter has its admirers, like many other deformities in and out of savage lands.

A New England spinster of many virtues recently remarked, with kind intent, to a New York girl, brought up *sans* heels, *sans* long skirts, *sans* big hats, *sans* everything that could in any way impede the natural movements of the body: "You hold yourself a trifle too straight. The Boston young women bend a little forward."

Then hapless infancy must submit to another infliction, and that is, white as the prevailing tone of its surroundings, unmodified even by the blue that spares somewhat the tender eyes of foreign infants who are dedicated to the Virgin. The well-bred baby has a white gown, is wrapped in a white cloak, tucked beneath a white blanket, in a perambulator protected from the sun's rays by a white-lined parasol. This is also "too sweet for anything." In winter the dazzling white of the snow is added to the general glare, and the baby winks and blinks in discomfort and steadily acquires bad muscular habits. The only prescription for this particular cruelty is to compel the parents to recline with upturned faces in the full glare of the sun, underneath a dome of white, surround them for several hours with a sea of white objects, and gently bounce them over unfriendly curbstones if possible. One month of long garments and broad hats for the fathers would banish æsthetic dressing from babyland forever.

A LEPER COLONY IN FINLAND.

Kuusamo is the name of a small town in Finland where leprosy has existed indefinitely, sixteen deaths from this disease having occurred there between 1774 and 1800, and twenty-two between 1801 and 1828. In an account of the settlement by Dr. L. W. Fagerlund, in the *Finska Läkaresällskapets Handlingar* for September, 1891, it is stated that the government, in 1767, sent to Kuusamo a physician, who was instructed to study the disease carefully and devise some remedy for its cure. His studies appear to have been barren of practical result, for in 1788 the chief medical officer of the district sent to the College of Medicine in Stockholm to inquire how his cases of leprosy should be treated. He was advised to use a decoction of wild rosemary leaves (folia rosmarini sylvestris) and also tincture of cantharides in doses of 12 to 30 drops. He was unable to overcome the malady by these means, and so in 1807 it was determined to isolate the sufferers, in order to prevent any further spread of the disease. A building was accordingly erected on a small island in Lake Kitkajärvi, and the lepers were removed thereto. Here they remained until 1845, often suffering from cold and hunger, in consequence of the neglect of those charged to carry wood and food for their use to the shore of the lake.

In 1845 the hospital system was abolished, and the medical officer of the district was instructed to visit the lepers twice a year in their own houses, and to report on their condition to the medical administrative body. These reports were made with regularity for twenty years and then ceased. In 1871 the physician reported that he was unable to find any more cases of leprosy in Kuusamo.

Between the years 1845 and 1865, during which period the semi annual reports were regularly presented, there were eleven cases of leprosy under observation. The evidence to be gathered from these reports as to the contagiousness of the disease is, as usual, indefinite and inconclusive. In one instance the disease appeared to have been communicated from a woman to her husband and to one of her children, and in another a young man seemed to have communicated it to his sister. On the other hand, two of the patients, who were poor and incapable of providing for themselves, were supported by the community, being passed along from one house to another after making a certain visit in each. No case of the disease was proved to have been caused by contagion spread abroad by these peripatetic invalids. Dr. Fagerlund discusses at some length the opinions held by different writers on this subject, but brings forward no new evidence for or against the theory of contagiousness, other than the meagre facts just cited.

A HINDU MEDICAL TREATISE.

The writings of the Grecian fathers of medicine have always exercised a peculiar charm over students of medical history, by reason of the wonderful knowledge of disease which these ancient physicians possessed, despite the limited means at their command for investigation and

study. They were deep thinkers and logical reasoners, and though we can no longer look to them as guides they will always be reverenced by modern students, and their works will be read with interest and profit by scholars as long as the world endures. Indeed, it is a constant source of pleasure to turn over the pages of such a master as Hippocrates, and learn how many of the principles there laid down are current and accepted even now.

But original as these workers were, they were not the founders of the healing art, and much of their knowledge was derived from older sources—from the Egyptians and other nations of antiquity. It is only within a comparatively recent period that the seals which kept Hindu literature from the knowledge of the West have been broken, but we are beginning now to realize that here is another well of ancient learning from which the Egyptians, the Greeks, and the Arabs doubtless drank deeply. We may not find here the fountain head of medical knowledge, but we seem to be nearer the source than ever before, and it may be that this is as near as we shall ever be able to approach it. It is, at any rate, an interesting field for the labors of the medical historian, and one which it will repay him to cultivate.

An ancient Sanscrit treatise on medicine has recently been discovered in Kashgar, bearing the title of "Navanitaka," and written apparently about the fifth century of the Christian era. But a more ancient work than this is probably the Charaka-Samhita, a translation of which into English[1] has recently been undertaken by Abinash Chandra Kaviratna, a practitioner of the Hindu system of medicine in Calcutta.

The exact date when Charaka wrote is unknown, though, as he is mentioned in the Purânas and by Avicenna and Rhazes, it was doubtless at a very remote period. The Samhita, however, was not his own work, but was a composition of Agniveça, founded upon the Ayurveda (Science of Life), which latter, tradition relates, came from the self-create Brahma. Whatever the origin of the treatise, its antiquity is undisputed, and moreover it is the foundation upon which rests the modern system of Hindu medicine. While we may not be able to agree with Dr. Sircar, who observed in an introduction to an English translation of the first chapter of the work that "there is much in it that even an accomplished physician will profit by learning," it is, nevertheless, a most interesting treatise. We read in it of the methods of treatment which were doubtless followed by the Hindu physicians whom Alexander the Great retained among his followers to heal the diseases which baffled the skill of his Greek physicians, and by the physicians who, many centuries later, practised in Bagdad, under the patronage of Haroun al Raschid.

Pundit Abinash Chandra Kaviratna deserves the thanks of all English-speaking scholars for his labors in translating this work, and we hope that the results of his venture will be such as to encourage him to follow it up with a translation of Susruta Samhita, the second great Sanscrit medical treatise, and one which may be regarded as the companion to Charaka's, of which he has already published a Bengali translation.

[1] Charaka-Samhita, translated into English and published by Abinash Chandra Kaviratna, editor of Chikitsa-Sammilani, etc. Calcutta: Printed by D. C. Cass & Co. 1890.

News of the Week.

A Wealthy Hospital. — St. Luke's Hospital, of this city, appraises the land on which it stands at $2,500,000. If it sells at this price, and no doubt it can eventually do so, the hospital, with its present rich endowment, will be wealthy beyond the dreams of avarice and beyond appeals to charity. It is proposed to move the hospital up-town, in the neighborhood of the new cathedral.

A Pension Fund for American Nurses.—An attempt is being made to establish a national pension fund for nurses in this country. For this purpose a meeting was held in this city on Tuesday last, on invitation of Rev. George S. Baker, of St. Luke's Hospital. Mr. Henry C. Burdett, of England, the founder of the Royal National Pension for Nurses, who is Secretary of the London Stock Exchange, was present and explained the basis on which the English fund is operated. The English society has been in existence for about three years. An attempt has already been made to found an association in this country, and meetings have been held in Washington, Philadelphia, Baltimore, and Boston, looking to this result. A scheme has been drafted with the object of meeting the special difficulties under which nurses at present labor in regard to their savings, with a view to securing to a nurse adequate provision for the later years of her life, and assistance in temporary or permanent incapacity. The tables on which the scheme is based have been indorsed by the actuaries of the Mutual Life Insurance Company, of New York, which prepared them free of cost.

Dr. Jones's Case of Fever is likely to become historical. It was reported verbally before the Memphis Medical Society in May last. The doctor now gives us the written details in the *Memphis Medical Monthly*. The patient was a girl of fifteen, who had had an attack of tonsillitis during which she gained some experience with the clinical thermometer. After recovering from the tonsillitis, she was found one day to have a temperature of 109° F. During the next seven days her temperature ranged between 97½° and 152° F. The pulse never was above 120, and the fever did not appear to cause any serious discomfort. The temperatures noted at various times were 115°, 111½°, 138½°, 130° F. The temperatures were taken in the mouth, rectum, and axilla. A special Chicago thermometer was used, which like the other thermometers was eventually broken. It is difficult not to believe that the temperatures were caused by mechanical manipulation. Dr. Jones runs a pretty sharp race for the hyperpyrexia record with Dr. W. I. Galbraith, but the latter is as yet ahead, for his patient got up a fever of 171° F. But then she was twenty-three years old and married, while Dr. Jones's girl was only fifteen. We note that the effete monarchies of Europe can only produce records of a temperature of 114° F.

A Large Down-town Hospital.—It is reported that Chambers Street Hospital will be rebuilt and enlarged.

The Keeley Treatment for Inebriety.—The Keeley bichloride of gold treatment seems likely to prove as gigantic a "fake," and as interesting a psychological phenomenon, as the Keeley motor. There are being established Keeley institutes all over the country. Unhappy

victims of inebriety in this neighborhood are served with gold injections at a place in White Plains. Matters are not going entirely without friction, however. The death of a patient undergoing the "cure" has recently been announced; and lately we learn that a patient at White Plains, after being under treatment for four or five days, developed an attack of delirium tremens and came very near shooting several of his neighbors.

The International Congress at Rome.—A movement is on foot in St. Louis to charter a vessel and take over a party of medical men who wish to go to the Roman Congress. The vessel is to have a capacity of four hundred passengers, and the trip will last six weeks. Several places in the Mediterranean will be visited. Dr. N. Senn, of Chicago, is president of the association which is undertaking this project.

A New Cause for Dislocated Vertebræ.—A fourteen-year-old boy of Bethlehem, while playing foot-ball with a crowd of companions, was "held" by another boy having his knee on his neck. Result—dislocation forward of fourth cervical vertebra. This is, of course, the exception to the rule that foot-ball is a healthful game.

Dr. M. Rosenwasser was the name of the gentleman who took part in the discussion before the American Association of Obstetricians and Gynecologists, as apparent in our issue of October 10th, and not Dr. Rosenbaum, as erroneously printed.

German Dermatological Society.—It has been decided that the Third Congress of the German Dermatological Society shall be held at Vienna in the first week of September, 1893, under the presidency of Professor Kaposi. The meeting will take place in conjunction with the Second International Dermatological Congress, which is fixed for the same time and place. The latter congress was held for the first time in Paris two years ago. The Second Congress of the German Dermatological Society, recently held at Leipzig, was attended by one hundred and twenty-six members.

State Board of Medical Examiners—Minutes of the Question Board.—A meeting of the Question Board was held October 8, 1891, in the Regents' room of the State Capitol at Albany. The meeting was organized at 10.30 A.M. Present, Drs. Fowler, Moore, Searle, Wetmore, and Lewi, together with Dr. Watkins, Chief Clerk Gallup, and Mr. Boland, stenographer, of the Regents' office. On motion, Dr. Wetmore was elected Chairman, and Dr. Lewi, Secretary. The Committee immediately proceeded to arrange and revise the questions submitted. This work having been completed, it was moved by Dr. Searle that within a month four complete sets of questions be sent by each of the three sub-committees to the Secretary of the Board of Regents, on the subject of Therapeutics, including Practice and Materia Medica. Carried. It was moved, by Dr. Moore, that previous to printing the sets of examination papers, Dr. Lewi be requested to edit, arrange in logical sequence, and revise all questions to be submitted at the licentiate examinations. Carried. Meeting adjourned at 11.15 P.M., subject to the call of the Secretary of the Board of Regents.

Surgical Clinics at the New York Hospital.—Medical practitioners residing within a distance of, say, one hundred miles from New York, and desirous of attending the surgical clinics of the New York Hospital, will, by forwarding their names and addresses to the House Surgeon, Dr. Bolton, have mailed to them the regular operation notices.

Hypodermic Injections of the Juice of the Thyroid Gland have been found to act as a diuretic in myxœdema by Dr. Fenwick, and Dr. Murray has found that they modify the symptoms of that disease.

The Difference Between Man and Woman. — This perennially interesting subject has been scientifically treated by Dr. Harry Campbell, who points out, among other differences, the great recuperative power of women; they bear the loss of blood extremely well, and even the most sickly of them show an extraordinary power of fighting against exhausting diseases. Dr. Campbell says that he knows of few facts in biology more remarkable than this tenacity of life in women. Not in a few diseases merely is the mortality of the male sex greater than in women, but in almost all. The author's explanation of the fact is, that "men being more katabolic than women, and their nervous centres therefore more explosive, one would expect them to show the greater tendency to those disorders which are attended by an excessive expenditure of energy." The differences between the boy and girl in nervous organization are very marked. With the one exception of infantile hemiplegia, boys are more frequently affected than girls by idiocy, acute anterior poliomyelitis, pseudo-hypertrophic paralysis, meningitis, and epidemic cerebro-spinal meningitis. Girls are more frequently than boys affected by habit, spasm, and chorea. Suicide is much more common in boys than girls. If we are to regard—with Herbert Spencer—woman as to some extent an undeveloped man, we should expect the woman to resemble the child more than the man does, and this, Dr. Campbell believes, is the case.

The MEDICAL RECORD long ago pointed out the significant fact that between man and woman there is a *vas deferens*.

Fatal Cocaine Poisoning.—An English physician, Dr. Bright, of Bournemouth, recently died from an over-dose of cocaine.

The Secretary of the Iowa State Board of Health has made an official announcement that habitual inebriety on the part of a medical practitioner shall be held as "palpable evidence of incapacity," rendering the delinquent liable to the revocation of the certificate entitling him to practise in the State of Iowa.

A Medical Faculty at Constantinople.—It is announced that a Faculty of Medicine is about to be established at Constantinople, which will be the first institution of that kind founded in Turkey. The Sultan has sent Nafiliam Andan Pacha to Paris to collect information and to invite several representatives of the medical profession of France to proceed to Constantinople to assist in the organization of the new Faculty. His Majesty is said to take a keen interest in the matter, and he has already shown his zeal for the medical advancement of his country by introducing important reforms in the working and management of hospitals, not only in his capital, but throughout the whole of his empire.

The Georgia Law against Intemperance Among Medical Men.—*The Lancet*, referring to this subject, says: "We cannot defend the severity of the Georgian law, and our contemporary regards it as a deliberate insult to the practitioners of the State. A vice that has been so common, and withal so leniently regarded by mankind, is surely not to be treated, in a first conviction, so severely. The case is different where the vice is persisted in. Georgia is a State where there is almost an equal number of black and white citizens. It may either be that the vice is more common, or the belief in severe measures greater, than in other populations. In any case, while drunkenness is a vice to be discouraged, and even punished, by those that exercise discipline in the great profession of medicine, it is indefensible in a Legislature for one conviction to deprive a man of his professional status. The proper remedy for the State to adopt would be to reduce the number of competing medical schools which hold loosely the gates of the profession and which let in those who are unworthy, and out of this reduced number to constitute a Board who should have power to judge of the efficiency of schools and to exercise discipline over all admitted to the profession. A medical man who frequently gets drunk brings his profession into discredit, and his profession should have the right of judging him."

Honors to Virchow.—Virchow's seventieth birthday, which fell on October 13th, was celebrated, says the Berlin correspondent of the *British Medical Journal*, with much pomp and circumstance. So many congratulatory deputations had been announced that the Professor's house did not afford room for all, and the large banqueting hall of the Kaiserhof was therefore chosen for their reception. The first deputation to offer their congratulations was one from the Ministry of Public Instruction, headed by Dr. Bartsch, one of the chief officials of the Ministry. The next deputation consisted of the professors of the medical faculty, headed by the Dean, Professor August Hirsch. This deputation was followed by one from the Academy of Science, headed by Professor von Helmholtz. The deputation bearing an address from the Municipality of Berlin, presenting Professor Virchow with the freedom of the city, was headed by Dr. von Forckenbeck, the burgomaster, who referred in grateful terms to what the Professor had done to improve the health of the city. The address and the accompanying medal, sent by the scientific bodies of Great Britain, were presented by Dr. Semon and Mr. Horsley. Congratulatory addresses were also presented by the medical faculties of Amsterdam, Pavia, Kazan, Warsaw, Brussels, Stockholm, Moscow, St. Petersburg, Berne, Tokio, Upsala, Tomsk, and other places. The military surgeons, represented by Surgeon-General von Coler, and the naval surgeons, represented by Dr. Wenzel, also tendered their congratulations. After an interval of much-needed rest, Professor Waldeyer presented the gold medal, which has been subscribed for by Virchow's admirers in and out of Germany. A silver replica was presented to his wife, and bronze copies to each member of the family and to the scientific bodies which had contributed toward it. After the ceremony in the Kaiserhof Hotel a second meeting was held in the large hall of the Pathological Institute. Here an almost endless procession of learned bodies and other corporations, presenting gifts and addresses, defiled before Professor Virchow. The Berlin Medical Society, of which Professor Virchow is president, presented him with his portrait, painted by Professor Lenbach, the presentation being made by Professor von Bergmann. Next came deputations from the Berlin Society of Anthropology and Ethnology, the students of the University, the Physicians, the public hospitals, the medical journals, and various other bodies. Dr. Adolph Meyer presented a plant recently discovered by Baron Muller, of Melbourne, in the heights of the tropical mountains of Australia, which the discoverer had named the "Virchow plant." The proceedings, which had been commenced at 10 A.M., came to an end at 4.30 P.M. In the evening a commers, or reunion, of the friends of Professor Virchow was held in Kroll's Theatre, at which speeches were delivered by Herr Eugen Richter, leader of the Radical party, and others.

Despite all this glorification, Emperor William has refused to recognize Virchow by the bestowal of any honors.

Report of the Surgeon-General of the Army.—In his annual report Surgeon-General Sutherland shows that while the number of sick reports was larger than during the previous year, the number of men constantly sick—42.71 per 1,000—compares favorably with 44.12 in the previous year. The cases of treatment of alcoholism numbered 40.73 per 1,000 for the army, as against 41.43 in 1889, and 56.68, the average during the previous decade, and in this connection the Surgeon-General notes with satisfaction that so many of the larger posts are at the lower end of the list. A great improvement in the diet of the men has been made within the past year. The complaints concerning clothing were not so numerous as heretofore. Treating in detail the subjects of alcoholism the report says that drunkenness is on the decrease. The colored soldier is seldom on the sick-list from this cause. Every medical officer who refers to the canteen system approves of it, with the exception of one. From Fort Niagara, N. Y., the report comes: "A remarkable change has taken place in the habits of the men as to sobriety since the establishment of the canteen. Signs of intoxication are rarely seen and the guard-house is without occupants. Nearly all of the other reports are to the same effect; and, on the other hand, the commandant at Fort Leavenworth notes an increase in the number of cases of alcoholism since the sale of beer in the canteen was stopped." The canteen has relieved our military posts of one-third of the cases of alcoholism that formerly tended to the demoralization of the individual, infraction of discipline, assaults, injuries, and deaths. In conclusion it is recommended that at each post there be established a systematic course of athletic exercises to improve the physique of the men, as this does not follow from military drills.—*Boston Medical and Surgical Journal.*

German Spas.—The following are the numbers of visitors reported at a few of the German watering places during the past season: Aachen, 33,155; Colberg, 7,787; Elster, 4,621; Landeck, 2,394; Nauheim, 8,455; Oeynhausen, 6,148; Reinerz, 3,388; Salzbrunn, 3,548; Soden, 1,226½; Sylt, 7,411; Wildungen, 3,438.

Reviews and Notices of Books.

A Short Manual of Analytical Chemistry, Qualitative and Quantitative, Inorganic and Organic. By John Muter, M.A., Ph.D., F.R.S.E. First American, Fourth London Edition. Edited by Claude C. Hamilton, M.D., Ph.G. 8vo, pp. 204. Philadelphia: P. Blakiston, Son & Co. 1891.

The American student of chemistry will feel under obligations to Dr. Hamilton for the admirable manner in which he has edited Dr. Muter's work, adapting it to the needs of practical chemistry on this side of the Atlantic. The method, arranged on the principle of the course of instruction given at the London School of Pharmacy, has been conformed to the requirements of the United States Pharmacopœia. The chapter on urinary analysis has been enlarged and illustrated. The chapter on water analysis has been altered to correspond with Franklyn's methods, which are in use in this country. The detail arrangement of the text-book is most excellent, and its practical methods are in every way commendable.

Regional Anatomy in Its Relation to Medicine and Surgery. By George McClellan, M.D., Lecturer on Descriptive and Regional Anatomy at Pennsylvania School of Anatomy, etc. In two volumes. Vol. I., 4to, pp. 418. Philadelphia: J. B. Lippincott Co. 1891.

The author in the first volume of a valuable work has proven quite successfully the interest that can be infused into the study of a comparatively dry subject by the adoption of a somewhat original plan of presentation. As the title indicates, the different regions of the body are considered by themselves and viewed as a whole in the varied relations of component parts. He rightly considers that this is the only method by which anatomy should be studied by the advanced student. To this end he faithfully and laboriously made three hundred or more dissections of these regions, and reproduced many of them in carefully colored plates. His selection of parts has been eminently judicious, and demonstrate in a satisfactory manner the salient points for study and comparison. In the present volume the upper regions of the body are considered in detail, each showing different relations of organs in given planes of dissection. The medical and surgical landmarks are brought out quite clearly, thus offsetting the dry memorizing of names, with the practical knowledge of their significant relations in medical investigation and their relative importance in surgical operations. The plates themselves are of singular excellence, focussing every photographic detail of the actual dissection.

The author's practical method of treating his subjects cannot be too highly commended. His pages are full of valuable hints which cannot fail to be appreciated by the careful student who may seek to perfect himself in a study which lies at the foundation of all accurate knowledge of medicine or surgery. The book is well printed on fine paper, and with the superb illustrations makes a model volume.

Report on Cholera in Europe and India. By Edward O. Shakespeare, A.M., M.D., Ph.D., of Philadelphia, United States Commissioner. 4to, pp. 944. Washington: Government Printing Office. 1890.

The author of this exhaustive report was appointed in 1885 a commissioner of the United States by President Cleveland to study cholera in Spain and other countries where it was then prevalent, with a view of obtaining such data as might serve in preventing an invasion of the disease in this country. As a result of his labors in Sicily, Spain, and India he has given us an account of the disease which in practical value and scientific interest has never been equalled. It would be useless to attempt even an outline of the work, covering as it does nearly a thousand closely printed quarto pages, copiously illustrated with chromo-lithographic illustrations of infected areas, schematic charts, micro photographic studies of bacilli, and elaborate tabular statements digested from hundreds of official reports graciously placed at his disposal by foreign scientists. Suffice it to say, however, that the study of the disease based upon such exhaustive data will serve to settle many points connected with its etiology, pathology, and prevention which have heretofore been open to more or less question. To summarize some of the more important conclusions would be all that is necessary in introducing this valuable report to the attention of our readers. It has been shown that the comma bacillus is the infecting agent, and is capable of being carried long distances by means of soiled clothing and other personal effects, and must be conveyed to the system of another through the gastro intestinal tract, either by contaminated water, uncleanly hands, or infected food. There is no proof that it can be communicated through the lungs, and is therefore not contagious in the ordinary sense of that term. It is also shown that a certain susceptibility of the individual is necessary, and that its further spread can be prevented in the incipiency of an epidemic by careful isolation of the individual and prompt disinfection of the discharges. These and many other points are exhaustively elaborated throughout the report, and for any student of the subject nothing is left to be desired.

Index Catalogue of the Library of the Surgeon-General's Office, United States Army. Authors and Subjects. Vol. XII. *Reger-Shuttleworth.*

This volume includes 20,251 author titles, representing 8,022 volumes and 18,090 pamphlets. It also includes 6,603 subject titles of separate books and pamphlets, and 18,956 titles of articles in periodicals. It is equal in size and value of material to any of the preceding volumes, and is, as it should be, still under the editorial supervision of Dr. Billings.

Scientific Medicine in Its Relation to Homœopathy. By Professor Theodor Bakody, M.D., of the Buda-Pesth University. Pp. 60. Philadelphia: Boericke & Tafel. 1891.

This address was originally written for the laity, but the author unintentionally has branched out into the discussion of several important points in modern therapeutics. The special topic dominating the address is as to whether the tuberculin inoculations are or are not Hahnemannian in method. He finds some points of similarity therein, but there are many points of difference as well. The position of the writer may be defined as that of a scientific physician with homœopathic inclinations, though not ready to accept the system in its entirety. The address is well written and will repay careful reading.

Diseases of the Nasal Organs. By Whitfield Ward, M.D. Pp. 165. New York: G. P. Putnam's Sons. 1891.

A Manual of Diseases of the Nose and Throat. By Procter S. Hutchinson, M.R.C.S., etc. Pp. 127. Philadelphia: P. Blakiston, Son & Co. 1891.

Both of these manuals belong to the class of publications intended "to relieve the busy practitioner," etc., and are both without any originality if we except a few cuts of modifications of instruments. The latter manual is more fragmentary in description while covering more ground. It is hard to know exactly what to say about books of this kind, which are fairly showered upon the market at the present time. They are all alike. They are compilations from larger treatises spiced with a little of the writer's experience. They are as orthodox as the average sermon. Somebody must buy them or else the supply would fall off. We suspect that the medical student is the buyer in the majority of cases, for no conscientious practitioner would ever content himself with such meagre works as make up this class.

A Manual of Practical Hygiene. By the late Edmund A. Parks, M.D., F.R.S., Professor of Military Hygiene in the Army Medical School. Eighth Edition. Edited by J. Lane Notter, M.A., M.D., Fellow of the Chemical Society; Fellow of the Sanitary Institute of Great Britain; Member of Council of the College of State Medicine; Professor of Military Hygiene at the Army Medical School, Netley. Philadelphia: P. Blakiston, Son & Co. 1891.

It is an encouraging sign of the growing interest in the science of hygiene that its literature is ever increasing. Journal articles appear with more and more frequency and the publication of a new treatise on the subject is no longer rare. Yet in the rivalry of new works on the art of preserving health Park's "Hygiene" holds its own as a standard treatise, and the appearance of a new edition will be welcomed by many old friends. Dr. de Chaumont, the editor of three editions previous to this, died in 1888, and the revision of the work has been placed in the hands of Dr. Notter. All who examine the book carefully, as we have done, will agree with us that he has done his work well, and that the high standard taken in the first edition is fully maintained in the present. The work has been brought fully up to the times, and this is saying much in these days of rapid progress in sanitary science.

Massage for Beginners; or, The Masseuse's "Vade Mecum." By Lucy Fitch. Pp. 32. London: Sampson Low, Marston & Co.

This is No. 4 of the "Nursing Record Series," and contains simple and easy directions for learning and remembering the different movements made use of in the art. The book should be in the hands not only of professional manipulators but also in those of all nurses.

Wood's Medical and Surgical Monographs for August. Contents: "Modern Abdominal Surgery," by Sir T. Spencer Wells, Bart.; "Subjective Noises in the Head and Ears, their Etiology, Diagnosis, and Treatment," by H. MacNaughton Jones; "Notes on Surgery, for Nurses," by Joseph Bell, M.D.; "Surgical Treatment of Typhlitis," by Frederick Treves, F.R.C.S. Pp. 253. Price $1. New York: William Wood & Co., 56 and 58 Lafayette Place.

No more valuable and timely work has appeared in "Wood's Monographs" than this one. The two articles on abdominal surgery are worth several times the price of the book. Sir T. Spencer Wells discusses anæsthesia, drainage, uterine tumors, enterectomy, oöphorectomy, Cæsarean section, Porro's operation, and the surgery of the kidney, liver, and gall-bladder. His paper is the work of a master, and admirable in every respect. No less worthy of warmest praise is the article on "Typhlitis," by the famous surgeon, lecturer, and author, Frederick Treves. The two remaining essays will interest and be of immense value to the classes for whom they are respectively written. Dr. Jones's work on "Noises in the Head and Ears" is a masterly one, complete, scientific, and most excellently written.

Norris's Nursing Notes. A Manual of Medical and Surgical Information for the Use of Hospital Nurses and Others. By Rachel Norris, R.R.C., Late Acting Superintendent of Royal Victoria Military Hospital at Suez, and formerly Matron to St. Mary's Hospital, W. Pp. 184. Illustrated. London: Sampson Low, Marston & Co.

This book is the second of a most excellent series for nurses, being issued by the English journal *The Nursing Record*. All are good, but the one in hand is of unusual value to nurses. It contains Anatomy, Physiology, Surgery—in short, it is a storehouse of necessary information that can be obtained elsewhere only with great difficulty and long research. The anatomical illustrations are good.

Society Reports.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Seventeenth Annual Meeting, held in St. Louis, Miss., October 14, 15, and 16, 1891.

First Day, Wednesday, October 14th.

The Association convened in the Pickwick Theatre, and was called to order at 10.30 A.M., by Dr. I. N. Love, Chairman of the Committee of Arrangements.

Prayer was offered by Bishop D. S. Tuttle.

The Address of Welcome was delivered by Hon. E. A. Noonan, Mayor of St. Louis, which was followed by addresses on the part of the State Medical Association by Dr. W. B. Outten; the St. Louis Medical Society, by Dr. Ludwig Bremer, its President, and remarks by Drs. Harold N. Moyer, and J. C. Culbertson, of Chicago.

After the report of the Chairman of the Committee of Arrangements, which was an interesting and attractive one, Dr. C. H. Hughes, of St. Louis, took the chair, and declared the Association ready for the transaction of its scientific work.

The Toxic Effect of Tobacco Vapor, with Report of Cases, was the title of the first paper, read by Dr. W. Carroll Chapman, of Louisville. He said that usually the presence of tobacco poison in the systems of tobacco workers is manifested during the first day or two by violent vomiting, retching, purging, and often a state of collapse, after which the system may become inured to it. Occasionally we find one whose constitution, even by contact and time, although there is a certain amount of toleration, refuses to receive it kindly, and emaciation begins, attended, sooner or later, by such symptoms as the following case illustrates:

Case I.—Willie C——, aged ten, was found suffering extreme pain in the abdominal region, with the intensity centring at the umbilicus. Temperature, under the tongue, 100° F.; pulse, 108, small, wiry, and irregular; respiration, 20 to 22, but irregular—several short, shallow respirations, followed by one deep and gasping. Tongue glairy, red appearance, and pointed. Patient constipated for the last several days; abdomen flat, or rather depressed; urine scanty, and slightly colored; skin dry, as were the hands and feet, the latter being a little cold. When near the patient the odor of tobacco was so pronounced that the doctor made inquiries regarding it, and learned that he worked in a tobacco stemmery, and further, that he had slight attacks of similar pains at several different times, except of milder form.

As to the nicotianin, indications point strongly to its being a cause. According to Landerer, it occurs only in dried tobacco leaves, and has the odor of that plant; a point strongly in its favor, as that odor was so distinct in every case the author had seen. It would seem, further, that the basic substances and fatty acids were causative agents, because authors have proven, by physiological experiments, that these cause contraction of the pupil, dyspnœa, abdominal pains, convulsions, and death.

The author directed attention to two factors, noticeable in all the cases, namely—the emaciation, and the time each one had followed the occupation, that is, from six weeks to three months. The three cases which he reported had not suffered from the vomiting and retching usually attendant upon young tobacco-workers the first day or two. In the other, or milder cases, he neglected to inquire regarding that point.

The toxic effect of tobacco vapor and its treatment was a subject worthy of more consideration than the profession has accorded to it in the past, and he hoped that the next few years, aided by diligent and careful investigation, would place the matter in a more intelligent light.

The Treatment of Typhoid Fever was the title of a paper read by Dr. Robert C. Kenner, of Louisville,

Ky., in which he directed particular attention to the cold-bath treatment.

Pelvic Inflammation in Women; A Pathological Study.—Dr. William Warren Potter, of Buffalo, followed with a paper on pelvic inflammation, in which he held that these and their residues constitute about one third of the diseases that gynecologists treated. hence the importance of frequent discussions of all moot questions relating to the subject. He briefly reviewed the anatomical relations of the pelvic organs, calling attention to their enormous blood and nerve supply, which became both their weakness and their strength. He contrasted the pathology of Bennet (1843) with that of Emmet (1873), and the latter with the teachings of Price, Tait, Hegar, and McMurtry, of the present age. He referred to the pathological studies of Bernutz and Goupil, of thirty years ago, and affirmed that the observations of the present had served to confirm the correctness of those pioneers.

He next asserted that the pathology of to-day had been established by operative surgery, which had shown that pelvic inflammation begins in the tubes or ovaries and extends to adjacent structures through absorption or by contiguity; that it almost never begins in the cellular tissue, but may be carried there through the tubes and ovaries, by infections, either specific, puerperal, or traumatic. He affirmed that the inflammation was in most cases a peritonitis, intra pelvic or local in character, and not a cellulitis; that para- and perimetritis were misleading and confusing terms, hence, should be dropped; and that the so called pelvic abscess was a sequence of salpingitis, ovaritis, or peritonitis, not a primitive accumulation in the areolar tissue itself.

The tentative management in these cases—rest, counter-irritation, hot sitz-baths, vaginal douches, and attention to the digestive organs and general health—resulted in only temporary improvement, or in cure in a very small percentage. Those reported cured were generally, if the history could be known, subject to repeated relapses; and a frequently recurring pelvic peritonitis usually indicated leaky tubes. Electricity, too, had disappointed even its most sanguine advocates, and need not be considered.

In conclusion, he asserted that if these views be accepted the logical deduction was to watch the early manifestations of the disease carefully, that competent surgical skill be invoked before the damage to important structures becomes too great to justify the expectation of successful operation.

Pathology and Surgical Treatment of the So-called Strumous Inguinal Lymphadenitis.—Dr. L. T. Riesmeyer, of St. Louis, read a paper with this title. The author adopted the view of Culvert and Klotz, that the majority of cases known under the name of strumous buboes, indolent sympathetic buboes, hyperplastic lymphadenitis, etc., are caused by the absorption of pyogenic material and are not due to scrofula, tuberculosis, or syphilis. Out of the forty-three cases which he reported, the majority had been suffering from a gonorrhœa six months to five years before they presented themselves. Three patients had chancroids, and one a syphilitic chancre a number of months before they came to be treated for the lymphadenitis. In five cases the swelling of the groin was attributed by the patient to the lifting of a a heavy load, while for the rest no cause was ascertainable.

As a rule, the patients came during the later stages of the disease and presented the following symptoms: Face pale and ash-colored, loss of appetite, a tired feeling, pains in the limbs, chilly sensations alternating with sensations of heat, night-sweats. Temperature varying between 100° and 102° F. Upon examination a large, nodular tumor, irregular in form, often fluctuating at one or more points, was found in one or both groins. The skin covering the tumor was, in contra-distinction to the virulent bubo, of a livid blue color, and is not unfrequently perforated by one or more fistulous tracks. There was usually but little pain upon pressure. In all cases the glands contained a great many miliary abscesses, otherwise only showing a hyperplasia of the connective tissue and medullary lymphatic tissue. Of micro-organisms staphylococci and streptococci were found. Hypertrophied lymphatic vessels ran over and through the substance of the glands.

In some cases the glands presented one large fungous mass, in which no individual glands could be made out. The time of development into the tumor, as described, varied between six months and three years. No tuberculosis was found among the cases, and after the operation the patients presented a strong and healthy appearance.

The glands should be removed before the pus has broken through the capsule, otherwise the patients are exposed to many dangers.

To extirpate the glands, the method recommended by Poelchen, of first exposing the internal saphenous vein by a vertical incision and dissecting along this vessel, leaving it intact upon the fascia lata, is the most rational. The glands are in this way removed quickly and without endangering the femoral vessels. In conjunction with Dr. L. P. Pollman, the author of the paper has had occasion to locate this vessel topographically. After determining the location of the femoral artery, the internal saphenous vein is found exactly at the point of junction of the external with the middle third of a straight line connecting the pubic spine with the point of intersection of Poupart's ligament with the femoral artery.

Second Day, Thursday, October 15th.

Gastrostomy for Impermeable Stricture of the Cardiac End of the Œsophagus—Recovery—Subsequent Dilatation of the Stricture.—This was the title of a paper read by Dr. Arch. Dixon, of Henderson, Ky.

On July 14th of the present year Dr. Thomas W. Taylor consulted him in regard to a patient who was unable to swallow anything save liquids. Examination by means of œsophageal bougies revealed the fact that complete stenosis of the œsophagus existed at the cardiac end. Operation was at this time declined. Again on July 29th the patient consulted him, and after persistent effort he failed to pass the stricture with the smallest bougie. The operation was now consented to, and on August 4th, assisted by Drs. John Young Brown, W. M. Hanna, W. S. Stone, A. J. Lieber, and T. W. Taylor, Dr. Dixon did a gastrostomy after Hacker's method. When the stomach was reached a fold was caught between the fingers and partially drawn through the wound, where it was held by a silver pin, care being taken that the pin pierced the mucous membrane, as suggested by Weir, thus forming a support for the stomach in the wound and serving as a guide when the opening should be made into it to show that the cavity was reached. The peritoneal coat of the stomach was now stitched to the parietal peritoneum by a continuous suture which on either side of the wound included the skin. The peritoneum above and below was brought together by interrupted sutures, which embraced muscle, fascia, and skin as well.

The wound was now covered with iodoform collodion, over which iodoform gauze was placed, confined by adhesive strips. The opening into the stomach was purposely deferred until adhesions should have formed. On the morning of August 7th, the dressing was removed, a few drops of cocaine were injected into the fold of the stomach which protruded through the wound, and the gastrostomy was completed by cutting down upon the pin with a tenotome. As in Weir's case, the presence of the pin was a valuable guide in showing beyond question that the cavity of the stomach had been entered. There was no hemorrhage of moment. The adhesions being firm, the pin was withdrawn and the mucous membrane was drawn up and stitched to the skin. A rubber tube was

now passed into the stomach through the opening, fitting it snugly. The wound was dressed with iodoform gauze and borated cotton. Peptonized milk, half pint, with a teaspoonful of Mosquera's beef meal, was now injected through the tube into the stomach by means of a large syringe. An ordinary spring clothes-pin was used as a clamp for the tube. Six hours later another half pint of milk with the beef-meal was thrown into the stomach, the patient experiencing a satisfaction which had not been felt previously from the use of nutritive enemas. The temperature at 8 P.M. reached 101° F., but at 10 A.M. on August 8th it had again fallen to normal. The feeding was continued at intervals of six hours, the food being varied in character—chopped meat, eggs, bread, etc. The patient had an aversion to brandy, and would take no stimulant of any character. Improvement was steady, and in ten days the patient was out of bed.

On August 29th, twenty-four days after the primary operation, Dr. Dixon determined to try dilatation, and was agreeably surprised to find that the smallest size olive-pointed bougie entered the stomach, passing the stricture without difficulty, a size larger was now used and it passed also without force. The following day a large stomach-tube was passed down the œsophagus and with little difficulty entered the stomach. Dilatation was continued at intervals of a few days. From liquid food the patient soon essayed some solid food, and on September 10th took his first square meal, which consisted of oysters, broiled beefsteak, coffee, eggs, and bread. On September 23d the patient complained again of difficulty of swallowing solid food; especially was there difficulty in swallowing bread. The bougies passed the stricture easily on entrance, but on withdrawal there was a decided hitch, even the smallest bougie was caught slightly when withdrawn. Dr. Dixon at first attributed this to spasmodic action, but the difficulty grew greater and greater, until finally he could no longer enter the stomach by way of the œsophagus with a bougie. Liquids could still be swallowed and found their way into the stomach. He now determined to try retrograde dilatation, and on September 30th, assisted by Dr. John Young Brown, he succeeded in finding the cardiac end of the œsophagus and entering it with a very small bougie-à-boule. The opening was about the size of a very small shirt-button hole, and felt much like the meatus urinarius in a girl; it was surrounded by a hard tissue, feeling much like a fibroid. A uterine sound was next properly bent, and with the finger as a guide, passed into the œsophagus; this was followed by a uterine dilator, slight pressure on the handles opened the blades almost half an inch, but the patient experienced so much pain that it was deemed best to desist. The following day chloroform was administered and retrograde dilatation was accomplished.

Up to this time the author had not been able to determine whether the stricture was due to malignant trouble or not, but on passing the finger into the non-dilated œsophagus, a friable irregular growth was detected, which easily broke down and bled rather freely. Since the dilatation the patient has been able to swallow solid food without much difficulty, and has notably improved in flesh and strength, and is able to attend to some business.

The author wished to acknowledge his indebtedness to Dr. Robert F. Weir, of New York, for many valuable suggestions, both in the performance of the operation and in the management of the case afterward, gleaned from his report of a similar case published in the MEDICAL RECORD, July 25, 1891.

Dr. Dixon also exhibited the patient to the Association.

DR. L. CH. BOISLINIERE, of St. Louis, exhibited a new obstetric forceps of his own design.

The Influence of Graveyards on Public Health.—DR. J. W. CARHART, of Lampasas, Tex., contributed a paper on this subject, in which he drew the following conclusions: 1. From whatever stand-point this subject is approached it must be with care and gentleness, since the graveyard, though a constant menace to public health, has a pseudo sacredness fostered by the profoundest sentiments of our natures. 2. The method of the disposal of the dead should be founded on reason and not on custom or sentiment. 3. The interment of the dead in the earth was never enforced by a statute, Jewish or Christian, and was merely incidental to both dispensations. 4. No law, human or divine, requires us to dispose of the dead in a manner prejudicial to the health and comfort of the living. 5. While it may be an open question as to the right of the State to decide as to the manner of the disposal of the dead, except in exceptional cases, it is clearly the province and duty of the State to prevent such disposal as will in anywise jeopardize the interests of the living. 6. From all the facts at our command, we are led to the conclusion that the graveyard should become a thing of the past, and that incineration is the method most in accordance with science, sanitation, æsthetics, reason, and religion. 7. We would add, as a corollary to these several conclusions, that since the intelligent, broad-minded physician is the almost exclusive guardian of public health in seeking to prevent the development and spread of disease, it is plainly his duty, when cemeteries are being located, to use his best endeavors to have them so placed as to jeopardize as little as possible the public health; and for its moral effect he should encourage efforts to beautify existing cemeteries; and that he should seek, as fast as possible, without too much violence to the tender sensibilities of the masses, to encourage incineration of the dead, or some other method more in harmony with sanitary science than the common modes now practised.

Dr J. T. Jelks, of Hot Springs, Ark., read a paper on "Blennorrhœa;" Dr. Landon Carter Gray, of New York, one on "The Present Aspect of Cerebral Surgery," in which he epitomized the work of Horsley, Ferrier, Keen, and others; and Dr. John A. Larrabee, of Louisville, Ky., one entitled "The Importance of Recognizing a Temporary Rachitic Condition in Infants."

Pachymeningitis Hæmorrhagica Interna.—DR. F. C. HOYT, of St. Joseph, Mo., read a paper with this title, in which he suggested the following deductions, offering them as a practical and rational view of the subject: 1. That the disease known as pachymeningitis hæmorrhagica interna chronica is not a disease of the dura mater primarily, and not necessarily at all. The name is therefore a misnomer, and the simpler term sub-dural hæmatoma should be substituted. 2. That the condition is due primarily to paralysis or loss of the normal vaso motor tonus, associated with structural changes in the cerebral vessels, particularly those of the pia mater. 3. That hemorrhage may, and often does, take place in the substance of the dura from the causes stated in the paper, but that its vascular supply and anatomical structure render it improbable that these hemorrhages play any part in the formation of a sub-dural hæmatoma. 4. That the hemorrhage occurs from the vessels of the pia mater primarily, forces its way without difficulty through the upper web-like layer formerly called the arachnoid, escaping into the sub-dural space. The extravasated blood becomes organized, new vessels are formed, and these assist in furnishing the recurrent hemorrhages. 5. That the inflammation of the internal surface of the dura mater is secondary and due to the irritation of the extravasation, and then is not general, but occurs only in patches where organic union has taken place.

Camphor-menthol in Catarrhal Diseases.—DR. SETH S. BISHOP, of Chicago, reported a large number of cases of naso-pharyngeal catarrh, hay fever, and diseases of the ear as having been treated with camphor-menthol with much better results than menthol alone produces. The presence of the camphor appeared to intensify the action of menthol. A number of hay-fever sufferers had obtained greater relief from this inhalant than from any other they had ever tried. The effect of the camphor-

menthol in reducing turgescence and consequent tumefaction of the turbinated bodies rendered a contemplated operation for stenosis unnecessary in several cases cited.

In some cases of constricted Eustachian tubes injections of a ten per cent. solution in lanolin had caused them to become patulous. The improved ventilation of the middle-ear thus effected, together with inflation with a five or ten per cent. spray of the same liquid in hypertrophic tympanic catarrh, increased the hearing and produced a sense of clearness and comfort in the head. Cases of laryngitis with the voice reduced to a whisper were treated with inhalations varying from five to twenty per cent. in strength, with the result of restoring the voice completely in from twenty four to forty-eight hours. No ill results had followed the use of this remedy in the nose, throat, larynx, or middle ear. The ordinary strength of inhalations recommended by Dr. Bishop were three or five per cent., for very susceptible or sensitive individuals like hay-fever patients, and ten per cent. for less nervous persons with hypertrophic catarrh, etc. In order to reduce great swelling of the turbinates and relieve stenosis the solution should consist of twenty or twenty-five per cent. of the camphor menthol. The full strength of camphor-menthol applied to eczematous eruptions relieved the itching and dissipated the redness and swelling. Similar results followed its application to herpetic eruptions. Finally, camphor-menthol contracts the capillary blood-vessels of the mucous membrane, reduces swelling, relieves pain and fulness of the head, or stenosis, arrests sneezing, checks excessive discharges, and corrects perverted secretions.

Dr. F. King, of New York, read a paper in which he advocated the poro-plastic felt jacket in the treatment of spinal troubles.

President's Address.—At the evening session the Association was called to order by the Second Vice-President, Dr. S. S. Thorn, of Toledo, O., after which President Hughes delivered his address on "Medical Progress." He reviewed the history and progress of medicine and surgery. He said it was gratifying to the humanitarian student of scientific medicine to note the amazing progress lately made in the knowledge of the human organism and in resources for its regulated control in health and disease. He referred to the wondrous laparotomies of Tait; the brilliant craniotomies of Victor Horsley; and the abdominal sections of Senn. He said the memory of Harvey, Jenner, Jackson, McDowell, and a host of others, is not yet fully appreciated by the world at large. But their deeds will shine brighter and brighter as the world comes to know them and fully realize, as we do, their incomparable benefactions, their unsurpassed greatness, and their unequalled heroism.

Dr. J. B. Hamilton, of Chicago, followed with an address on "The Drainage of Chicago," in which he principally dwelt upon its topography.

Dr. Joseph M. Mathews, of Louisville, then delivered an entertaining and humorous address on the "Lights and Shadows of a Doctor's Life." The address was punctuated throughout with great applause, and was a relief to the laity after listening to the profound, scientific, scholarly addresses of the preceding speakers.

At the close of the session the members repaired to the Lindell Hotel, where a banquet was given with all the manifestations of true St. Louis hospitality.

(To be continued.)

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting October, 1, 1891.

Alfred L. Loomis, M.D., President, in the Chair.

Library Donation.—The Academy accepted, with thanks to the family, the gift of the medical library of the late Dr. Fordyce Barker.

The Enlarged Prostate and its Surgical Relief.—Dr. Edward L. Keyes read the paper (see p. 525).

Dr. Samuel Alexander propounded two questions: 1. Why did operations upon the prostate, removing the obstruction at the neck of the bladder, restore, when there was vesical atony, voluntary urination? 2. Why did the author consider chloroform the best anæsthetic? He had performed four perineal operations, and most of them were unsatisfactory in that he could not remove a sufficient quantity of the obstruction from that direction. By using the écraseur in the manner suggested by Dr. Keyes, perhaps one would find operating through the perineum more successful. Another excellent suggestion contained in the paper was the use of the rongeur forceps in the suprapubic operation. In one of the two cases in which he had cut above the bone, the prostatic tissue was so hard and difficult to get at that he could not remove what he wished by the usual means, and he felt sure the rongeur forceps would have helped him out of the difficulty. He was glad the author had given us full warning of the dangers of the operation, which he had himself not so fully realized before.

Dr. L. Bolton Bangs said he had many times asked himself the question whether he ought to propose to his patients, old men, an operation on the prostate, with the hope of obtaining the relief from many troublesome symptoms which successful prostatotomy often gave, and he had answered in the negative; that he would attempt to make them comfortable by other measures, because of the risks and death-rate of operative procedures. Still, there were cases which required an operation, and the indications for the one or the other methods had been well pointed out by Dr. Keyes. He thought, however, that further consideration would have to be given the question whether cases should not be operated upon earlier. The period at which the operation was undertaken would probably have some influence on the mortality. He, too, appreciated the valuable remarks of the author on the technique of the operation.

Dr. John A. Wyeth had operated only by the suprapubic method. He made a vertical incision, very seldom a cross incision, over the pubic arch. He agreed with the author as to the uselessness of perineal drainage; said that in the twenty-four cases which he had operated upon he had employed siphon drainage with entire satisfaction after he had learned how properly to use it. In preparing the patient he made it a rule to sterilize the urine by administering five or six drops of the oil of gaultheria several times a day for two days.

Clings to Ether.—Dr. Wyeth could not understand why Dr. Keyes should now pass to the use of chloroform, an anæsthetic which the English were only just discarding to such an extent for the use of ether, the latter having been the favorite agent in America for so many years. It was not until recently that he had learned how to use ether in a way to get the maximum benefit out of the least quantity. No one, he thought, would discard it for chloroform, except in special conditions, after having once employed the Armstrong inhaler.

He thought suprapubic prostatotomy was not so dangerous as the paper would lead one to think. The danger arose from the condition the patient was in, rather than from the operation. But even in almost moribund subjects it offered a chance of restoring the patient to health, as in one instance which he mentioned, that of a man who had been confined abed for two years.

Dr. Keyes said he was unable to satisfactorily answer Dr. Alexander's first question. Regarding the second question, why he used chloroform, it was because in so many of these cases there was a pathological change which had extended to the kidney. Although the bladder walls might be thick, apparently hypertrophied, it was not a compensating, but a degenerative process. Chloroform was safer not only because less injurious to the kidneys, but also on account of the liability of ether to set up a bronchitis or pneumonia in this class of subjects.

Therapeutic Hints.

Carbolic Acid in Rheumatism. — Dr. J. L. Hancock writes in the *North American Practitioner* for September, 1891, upon the good effects of carbolic acid locally applied in the treatment of acute articular rheumatism. He uses it in the form of a four per cent. solution applied warm on a piece of flannel wrung out and enveloping the joint. This application is made at night, and allowed to remain until morning. It has given good results in the writer's hands.

Vaccination for the Relief of Whooping-cough.—Dr. Emile Müller reports in the *Gazette Médicale de Strasbourg*, No. 7, 1891, the case of a young child suffering from pertussis, in whom a cure was obtained by means of vaccination. Dr. Cachazo (*Wiener Medizinische Blätter*, October 16, 1890) had previously noted the favorable influence of inoculation with vaccine material in a case of whooping-cough under his care, and subsequently employed the method in four other cases with great success.

A Snuff for Acute Coryza.—Tissier recommends the use of the following snuff for the relief of a cold in the head:

℞. Menthol ..... gr. vj.
Powdered boracic acid ..... ʒ ij.
Subnitrate of bismuth,
Powdered benzoin ..... āā ʒ iij.

A good-sized pinch of this may be snuffed up five or six times a day. If desired, one grain of morphine and half a drachm of calomel may be added to the mixture, the addition apparently increasing its efficacy in certain cases.

Glycerine in Burns.—Grigorescu says that the application of pure glycerine to a burn relieves effectually and promptly the pain, and also favors a rapid healing. The sooner the application is made after the burn has been received, the more noticeable are the results. At first a slight smarting is felt, but this soon passes off and is succeeded by an almost entire freedom from pain.

Potassium Iodide in Chorea.—Dr. C. Semening reports in the *Allgemeine Medicinische Central-Zeitung*, No. 77, 1891, the case of a child suffering from marked chorea, which had resisted the action of arsenic, iron, bromide of potassium, and other remedies. He then ordered a solution of iodide of potassium, ʒ ss., in water, ʒ iv., a tablespoonful to be taken three times a day. After a few doses the choreic movements ceased entirely.

An Antiseptic Adhesive Pomade.—The following is employed in the Hôpital Saint-André, in place of adhesive straps, to keep the protective dressings in close apposition to the skin:

℞. Oxide of zinc ..... gr. x.
Chloride of zinc ..... gr. xlv.
Gelatine ..... ʒ x.
Water ..... ʒ ij.

It is also found very serviceable in dressing wounds of the face.

Flatulent Dyspepsia.—The following powders are recommended by a writer in the *Revue Générale de Clinique et de Thérapeutique* for the relief of flatulence occurring in various digestive disturbances:

In cases of dilatation of the stomach:

℞. Naphthol ..... gr. lxxv.
Magnesia ..... gr. cl.
Essence of peppermint ..... gtt. iij.
For 20 powders, one to be taken after each meal.

When diarrhœa is present:

℞. Powdered nux vomica ..... gr. xv.
Red cinchona bark
Prepared chalk ..... āā gr. lx.
Bicarbonate of soda ..... gr. lxxv.
Divide into 20 powders, and give one after each meal.

If constipation is present the following is preferable:

℞. Calcined magnesia,
Sulphur ..... āā gr. lxxv.
Divide into 20 powders, one to be taken after each meal.

When gastralgia is a prominent symptom cocaine may give relief, as in the following:

℞. Hydrochlorate of cocaine ..... gr. iij.
Sulphate of quinine ..... gr. xxx.
Prepared chalk ..... gr. lxxv.

For 20 powders, one powder to be taken after each meal. Care must be taken not to allow the use of this remedy for a long-continued period, because of the danger of thus laying the foundation of the cocaine habit.

The Odor of Iodoform can be removed from the hands and other parts, it is asserted, by washing thoroughly with linseed-meal water.

Senile Pruritus.—A German writer recommends sponging the body every night with warm water containing carbolic acid and vinegar, and the subsequent application of a powder consisting of one ounce of salicylate of bismuth and four ounces of starch.

Sore Nipples are often greatly benefited by an application of equal parts of subnitrate of bismuth and castor-oil.

Neuralgia.– Dr. W. M. Hightower recommends the following:

℞. Ammonii bromidi,
Sodii salicylatis ..... āā ʒ j.
Tincturæ hyoscyami ..... ʒ ij.
Aquæ ad ..... ʒ iv.
Sig.: One teaspoonful every half-hour until relief is obtained, or four doses have been taken.—Memphis *Medical Monthly.*

Inflammation of the Prostate.—The following is recommended by a French writer as very efficacious in the relief of chronic prostitis:

℞. Iodoform ..... gr. xx.
Olive-oil ..... ʒ ij.
Cocoa butter ..... q. s.
Divide into twenty suppositories, one to be inserted at bedtime.

A Laxative Powder.—The following is a favorite prescription of Dujardin-Beaumetz for the relief of chronic constipation (*L'Union Médicale*):

Cream of tartar ..... gr. xl.
Powdered aniseed,
Powdered fennel seed ..... āā ʒ j.
Powdered senna-pods,
Washed sulphur ..... āā ʒ ij.
Powdered liquorice-root ..... ʒ ijss.
Sugar ..... ʒ j.
Mix well. Dose: one dessertspoonful in water at bedtime, or whenever most convenient.

For Acute Gonorrhœa.—Dr. Schwimmer recommends injections of a solution of salicylate of mercury in the strength of ¼ grain to the ounce.

Diarrhœa.—The following dispensary prescription for diarrhœa is given in the Buffalo *Medical and Surgical Journal*:

℞. Salol ..... ʒ ij.
Subnitrate of bismuth ..... ʒ iv.
Chalk mixture ..... ʒ iij.

M. Sig.: One teaspoonful every two hours.

Fissured Nipples.—The following lotion for sore nipples is recommended in *Nouveaux Remèdes*:

℞. Balsam of Peru,
Tincture of arnica ..... āā ʒ j.
Lime-water ..... ʒ j.
Oil of sweet almonds ..... ʒ ij.

Enucleation of a Ruptured Eyeball.—Dr. James Ryley, writing in *The Lancet* of August 22, 1891, says that the enucleation of a ruptured eyeball may be easily performed if the globe be first stuffed with wool through the laceration in its coats, the edges of the gap being then united with a suture the ends of which are left long

enough to be of use in traction. If this be done, the operation will be found to be no more difficult than the enucleation of an unruptured globe.

Back-ache.—For the back-ache occurring with fever and at other times, Dr. H. E. Stroud, writing in the *Times and Register*, recommends equal parts of fluid extract of hydrangea and sweet spirit of nitre, in doses of one teaspoonful in water every two hours. He does not advise the mixture in back-ache for uterine displacement or in sciatica, but in all other forms he regards it as highly efficacious.

To Arrest the Secretion of Milk, the external application of one part of camphor in six parts of oil of turpentine is often of great service.

Chronic Diarrhœa.—The following has been recommended :

℞. Tannin..... 30 grains.
Rice flour,
Powdered chocolate,
Sugar, of each..... 2 ounces.

Put a heaping tablespoonful in a cup of boiling milk and boil a little longer, and serve with the morning and evening meals.

For Acne an application of corrosive sublimate in emulsion of almond-oil (1 part to 1,000) has been recommended.

Treatment of Old Ulcers of the Leg.—Dr. Charles P. Elwert, of New York, writes: "I have treated in the past six months, at Demilt, Bellevue, and Vanderbilt Dispensaries, and also in my private practice, forty-six cases of varicose and other ulcers of the leg, and have obtained favorable results in thirty-four cases by the following method : Cleanse the ulcer by irrigating with a solution of corrosive sublimate, 1 to 5,000. Then dry thoroughly with absorbent cotton, and apply daily the following powder :

℞. Iodoform..... ℥ ss.
Sulphate of cinchonidia..... ʒ j.
Wood charcoal..... ʒ ijss.

If any discharge appears after applying the powder, use absorbent cotton before applying the powder again. Advise the patient to rest and to keep the leg elevated. Keep the bowels regular with a mild laxative, and give some stimulating tonic to improve the condition of the general system. In the case of my four patients the powder caused irritation, and the discharge was increased. On further examination of those patients I discovered the existence of Bright's disease. In six other cases, where the above treatment was not successful, a poultice composed of powdered wood charcoal and matricaria was used for three or four days, until I obtained a healthy appearing surface to the ulcer ; and I then applied daily the following solution :

℞. Tr. calendulæ..... ℥ ij.
Aquæ camphoræ..... ℥ viij.

After applying the solution, I strapped the ulcer with adhesive plaster, with good results in four of the above six cases, and gave laxatives and a tonic. As the treatment of chronic ulcers at the present day is not very successful in a large percentage of cases, especially in dispensary practice, the above treatment may be of use to the profession."

The Administration of Bromides.—The *Bulletin of Pharmacy* for September, 1891, calls attention to Professor Feré's recent suggestion concerning the administration of bromides. Believing that large doses sometimes induce unpleasant symptoms in consequence of a condition of sepsis in the intestinal tract, he recommends the administration of intestinal antiseptics, like naphthol, to remove drug intolerance due to the foregoing or other cause. The following formula has given excellent results, especially in the treatment of epileptics :

℞. Potassium bromide..... 1½ drachm.
Beta-naphthol..... 1 drachm.
Salicylate of sodium..... ½ drachm.

Mix and divide into three doses, one dose to be given three times daily.

It is affirmed by Feré that this treatment is curative and preventive. To this formula some French physicians add one-thirtieth of a grain of quinine sulphate. Eczema and psoriasis following the use of borax, also disappears if the intestinal tract is rendered aseptic.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

SPURIOUS ARTHRITIS FROM NERVE LESIONS—DISEASE OF THE SEMINAL VESICLES—UNION OF SKULL-BONES AFTER FRACTURE AND TREPHINING—MEDICAL MIGRATIONS—THE WELSH LANGUAGE IN MEDICINE—THE GUILD OF ST. CECILIA.

London, October 17, 1891.

The Clinical Society commenced work for the winter last week. Dr. Maclagan read a paper in which he gave an account of three cases of neuritis in which spurious arthritis followed the nerve-lesions. The latter affected the nerves of the arm and changes occurred in the joints of the knuckles and fingers. These changes were non-inflammatory in nature and consisted essentially in contraction and diminution in size of the bony and ligamentous structures of the joints ; the author believed that they were the result of malnutrition of the affected structures, and that they were produced in the same way as the wasting of the muscles and the glossy state of the skin by which they were accompanied. The cases had nothing in common with true arthritis, and there could be no difficulty in distinguishing between the two conditions. The malnutrition of spurious arthritis was connected with the peripheral derangements accompanying peripheral neuritis.

Mr. Bowlby said he had had the opportunity of examining the joints of the hands in cases in which the median and ulnar nerves, with the tendons, had all been divided years before. The fingers showed the condition described by Dr. Maclagan and other changes had occurred in the articular cartilages themselves. With long fixation in one position the changes in a joint might after a time become inflammatory and intra-articular, but he believed they were always at first extra-articular. He had seen hands which it was formerly thought were quite incurable become enabled to continue their former work quite well, and he now considered the joint changes were generally such as admitted of recovery.

Dr. Barlow said he had seen some cases of spurious arthritis. They had generally been associated with alcoholic neuritis and occurred especially in the ankle-joints. If such cases were seen early, he would urge the use of a bed-cradle to take off the weight of the clothes, so that there might be no necessity for the patient to keep the attention fixed on the joints. He thought peripheral neuritis was often found in the early stage of infantile paralysis. He had noticed in cases of that condition great tenderness about the legs, and often a red swelling about the dorsum of the foot, almost simulating a gouty attack ; this was probably an acute form of the condition which Dr. Maclagan had described as the chronic stage.

Dr. Maclagan, in reply, said the treatment of his three cases had consisted in forcible movements, electricity to restore the tone of the muscles, and gentle massage; in one case the cure was completed at Wiesbaden. One patient had quite recovered, and could now play the piano as well as before being ill. If the patients were left long without treatment the joints were liable to re-

main permanently altered, but he thought the cases were curable if taken at an early stage.

Dr. Parkin read notes on two cases of chronic disease of the seminal vesicles. Mr. Bruce Clarke related two cases of compound fracture of the skull in which the fragments of bone were carefully replaced in position and became firmly united. Mr. Arbuthnot Lane and Mr. W. H. Bennett also mentioned cases in which they had replaced bone removed in trephining, and found it unite firmly.

Dr. David W. Finlay, one of the physicians to the Middlesex Hospital, is just leaving London in order to take the position of Professor of Medicine at the University of Aberdeen. This is a striking illustration of the way in which the Scotch University system works. When a professorial chair is vacant the choice of the electors is by no means limited to local talent, nor even to Scotchmen. In the present instance Dr. Finlay, though a Scottish graduate, is not an alumnus of Aberdeen University, and has been established in London as a physician for about fourteen years. As other examples of Scottish Professors chosen from the London schools I may mention Sir William Turner, who has now been for many years Professor of Anatomy at the University of Edinburgh, but who studied at St. Bartholomew's Hospital, and graduated at the University of London; Dr. Greenfield, now Professor of Pathology at the same University, who received his medical education at St. Thomas' Hospital and, after graduating at the London University, held appointments at St. Thomas's and other London hospitals. Sir Joseph Lister, also, though an alumnus of University College and London University graduate, went north, where he became Professor of Surgery at Glasgow and Edinburgh Universities in succession, only vacating the latter position in order to come south again to hold the position he now occupies at King's College. Instances of this latter migration—southward—are not uncommon, and I could easily frame a long list of Scotchmen and Scotch graduates who have come to the metropolis and achieved success, but this is not so surprising considering the superior advantages n private practice offered by the southern capital.

The recent action of the Royal College of Physicians and Surgeons in Ireland emphasizes the fact that we are still a polyglot nation. The bodies in question have just recognized Welsh as one of the optional subjects for the medical preliminary examination and accept it instead of French and German. Our friends in the principality ought to be proportionately gratified. The Welsh language, however, promises to be longer lived than any other of the languages originally spoken by the inhabitants of the British Isles. Erse is well-nigh extinct and Gaelic is only spoken in the remote highlands of Scotland. Welsh, however, is still an important living language and a knowledge of it is imperative for the practitioner who settles in the rural parts of Wales, where many of the inhabitants speak no other tongue. Practitioners thus situated, when advertising for assistants, generally specify that a speaking acquaintance with Welsh is essential. The probable establishment of a Welsh University in the not-far-distant future is likely to still further encourage the study of the language of the ancient Britons.

Under the name of "The Guild of St. Cecilia" an organization has been established to use music as a therapeutic agent, and favorable examples of its beneficial action have already been obtained.

PRISON MANAGEMENT.

To the Editor of the Medical Record.

Sir: I have always read what Henry A. Riley, Esq., of New York, has contributed to the Record on medico-legal subjects with interest and profit, and have taken occasion to call the attention of physicians to important questions furnished by him to the professional reader as constituting a valuable department of journalism.

In the last issue of the Record, under the sub-title of "Convict Leasing and Prison Management," he uses the following language: "In this State charges have been made by the daily papers of great cruelty in the punishment of prisoners at the Clinton State Prison. The charges are direct and circumstantial and deserve a careful investigation, although the Superintendent of the State Prison is reported to consider them beneath consideration."

To correct the error into which Mr. Riley has inadvertently fallen, in the foregoing quotation, I would state that, at the present time a commission composed of Mr. Oscar Craig, President of the State Board of Charities, Mr. William M. F. Round, Secretary of the New York State Prison Association, and Dr. Leroy Balch, Secretary of the State Board of Health, designated for the purpose by General Austin Lathrop, Superintendent of Prisons, is in session at the Clinton Prison, to investigate the charges which have been current in the newspapers, in respect to cruel practices in that institution.

The character of the commission gives assurance of the thoroughness with which the investigation will be conducted.

William C. Wey, M.D.

Elmira, N.Y., October 18, 1891.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 18, 1891, *to October* 24, 1891.

Biart, Victor, Captain and Assistant Surgeon. Having been found incapacitated for active service on account of disability incident to the service, is, by direction of the President, retired from active service, to date October 21, 1891.

Vickery, Richard S., Major and Surgeon. Relieved from duty at the Army and Navy General Hospital, Hot Springs, Ark., and ordered to duty at Fort Monroe, Va.

Munn, Curtis E., Major and Surgeon. Upon being relieved from duty at Fort Monroe, Va., is ordered to duty at Mount Vernon Barracks, Ala.

Cleary, Peter J. A., Major and Surgeon. Upon being relieved from duty at Mount Vernon Barracks, Ala., is ordered to duty at Fort McPherson, Ga.

Happersett, John C. G., Major and Surgeon. Upon being relieved from duty at Fort McPherson, Ga., is ordered for duty at Fort Custer, Mont.

Gardner, Edwin F., Captain and Assistant Surgeon. Will proceed from Fort Porter, N. Y., to New York City, for temporary duty as Attending Surgeon and Examiner of Recruits in that city.

Waters, William E., Major and Surgeon. Upon being relieved from duty at Fort Custer, Mont., is ordered for duty at Columbus Barracks, O.

Jarvis, Nathan S., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Bayard, N. M., and ordered for duty at San Carlos, Ariz. Ter.

Johnson, Richard A., Captain and Assistant Surgeon. Upon being relieved from duty at San Carlos, Ariz. Ter., is ordered for duty at Fort Bayard, N. M.

Brooke, Benjamin, First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Riley, Kan., and ordered for duty at Fort Leavenworth, Kan.

Keefer, Frank R., First Lieutenant and Assistant Surgeon. Upon being relieved from duty at Fort Leavenworth, Kan., is ordered for duty at Fort Riley, Kan.

MIDDLETON, PASSMORE, Major and Surgeon. By direction of the President, will report in person to Colonel Melville A. Cochran, Sixth Infantry, President of the Army Retiring Board, at Newport Barracks, Ky., for examination by the Board.

GANDY, CHARLES M., Captain and Assistant Surgeon. Granted leave of absence for fifteen days, to take effect on final adjournment of Army Medical Board, now in session in New York City.

APPEL, DANIEL M., Captain and Assistant Surgeon. Granted leave of absence for one month, to take effect about 6th proximo.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 24, 1891.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	50	9
Scarlet fever	76	10
Cerebro-spinal meningitis	2	4
Measles	40	4
Diphtheria	84	20
Small-pox	0	0
Varicella	0	0
Pertussis	1	3
Erysipelas	0	0
Mumps	0	0
Röthein	0	0

Hysteria and Tremulousness in Males.—Hysteria in men is apparently not rare in other countries, but in England it is, relatively speaking, very uncommon. Not many years ago a Russian physician observed that true hysterical fits were common among young Circassian men, and the disease might reasonably be suspected to prevail where men of an imaginative and impressionable stock predominate. Judging by the evidence of French medical publications, Frenchmen are far more subject to hysteria in adult life than Englishmen. Occasionally certain cases recorded in French medical newspapers must cause us to reflect; are such cases hysterical at all, or are certain nervous affections common in England really forms of hysteria? The doctrine that hypochondria is in males the homologue of hysteria, must be accepted by the French on the evidence of what prevails in England. For hypochondria, low spirits, or "spleen," is proverbially common there, and the French hold exaggerated opinions on the subject. In a more excitable race, more acute nervous symptoms might be expected. M. Debove has recently had under his care, in the Hôpital Andral, two cases of hysterical trembling. The first patient was aged fifty-four; he was well till last summer, when he was knocked down by a mounted trooper at a review. Violent tremors set in, simulating disseminated sclerosis, and he could not do his work at a sugar refiner's. He had plantar and pharyngeal anæsthesia and other symptoms of hysteria. Fifteen grains of bromide of sodium were given daily, and, with moral treatment, the patient recovered. The cure was sufficient to counter-indicate sclerosis. The second patient was aged thirty eight, but the case seems doubtful. He fell from a roof about a year since, and remained for over five months hemiplegic and aphasic. A fortnight before admission into M. Debove's wards the patient, returning home from work, found that his wife had deserted him. He fell down unconscious, and on recovering his senses he found that the limbs and body trembled violently. The tremors remained very severe in the right arm. The case, being compared to similar instances in women—held by Dr. Debove to be truly hysterical—was reported as hysterical trembling in a male subject. The history of an injury, with symptoms indicating, indeed proving, very definite cerebral lesions, may make many readers sceptical about the hysteria in this case. Yet it would be interesting to determine how far tremulousness in sober, fairly nourished men may be an evidence of true hysteria.—*The British Medical Journal.*

What is True Surgical Antisepsis.—At the last meeting of the Clinical Society of Baltimore, the whole evening was given up to a discussion on "Some Considerations Concerning Surgical Antisepsis," which was opened by Dr. William H. Welch. He defined the terms antisepsis and asepsis, and said we need antisepsis in order to obtain a condition of asepsis. In spite of the fact that no one now uses Lister's elaborate methods of disinfection, and there was much change since his first paper on this subject, we should not forget that Lister established a principle which still stands, we should admire him for this principle even if he did not understand some of the methods as we understand them now. A number of experiments had been made at the Johns Hopkins laboratory with the object of testing the germicidal power of corrosive sublimate solutions, and the results seemed to be interesting. While we do not believe that the air is literally swarming with bacteria, as some would have us believe, still we must not ignore this source of contagion, especially in a hospital. Before beginning an operation it is customary to cleanse the skin of the patient and the operator's hands. Simply washing with soap and water removed mechanically many bacteria, and indeed soap was itself a germicide of no mean power. After this it was customary to wash with a corrosive sublimate solution. As Dr. Halsted was not satisfied with the results of some of his operations, especialy in the healing of the wound around the sutures, they have begun a series of experiments.

The result of their experiments was to show that the germicidal power of corrosive sublimate was limited. To a germ culture of bacteria was added a certain amount of a corrosive sublimate solution, and the result was that, while most of the bacteria might be killed, some of them simply had their activity held in abeyance, while some were not at all affected unless large quantities of corrosive sublimate solution were added. It was also found that in some cases strong solutions were necessary, while in others weaker ones would do. In making cultures from the skin of the operator, large numbers of colonies were obtained, the soap and water was used and cultures were again made, with the result of finding a still smaller number, while a washing with corrosive sublimate solution showed very few. But laboratory experiments made him suspect that all these bacteria were not killed. To prove this, after washing with the corrosive sublimate solution, the fungus was washed with sulphate of ammonia, and then scraped and cultures made, with the result of finding many colonies. His reasoning was that what bacteria were on the hand after washing with soap and water, were partially killed by the corrosive sublimate solution, but that this solution soon ceased to be effective, and the mercury united with the albumin of the tissue to form the albumunite of mercury, which formed a capsule around the bacteria and micrococci, which would not grow when transferred to culture-tubes; but let the hand once be washed with sulphide of ammonia, and this dissolves off the capsule and sets the bacteria free, which then grow in culture media.

He had discovered also in the deeper layer of the skin a micrococcus which he called the micrococcus albus. He thought it caused the stitch abscess, which did not occur when subcutaneous sutures were used. One thing his experiments had taught him, that corrosive sublimate stays on the hands for weeks and months at a time, and this was proved by putting sulphide of ammonia on a hand which had not been in corrosive sublimate solution

for weeks and months, and the hand turned brown from the formation of the sulphide of mercury.

The most satisfactory disinfectant was permanganate of potash and oxalic acid in solution. The result of this careful work showed that corrosive sublimate was not always a reliable disinfectant, and the skin is not easy to disinfect. Several surgeons entered into a discussion, and the subject, viewed from the stand-point both of the pathologist and the surgeon, was fully developed.

Medical Diplomas Conferred and Refused in 1889–90 in France and Germany. — In the German Empire (45,000,000 inhabitants) the German universities conferred, in 1889 and 1890, 1,125 diplomas of doctor of medicine, distributed as follows: Berlin, 163; Bonn, 110; Breslau, 42; Erlangen, 69; Freiburg, 44; Giessen, 12; Göttingen, 25; Griefswald, 80; Halle, 36; Heidelberg, 22; Jena, 42; Kiel, 48; Königsberg, 26; Leipzig, 2; Marburg. 23; Munich, 114; Rostock, 6; Strassburg, 63; Tübingen, 22; Würtzburg, 166. The number of doctors rejected in 1888–89 was 1,030; in 1887–88, 935; in 1886–87, 847; in 1885–86, 685. In France (38,000,000 inhabitants, not reckoning the colonies) the number of doctors rejected in 1889–90 by the six French faculties was 597, a decrease of 28 on the year preceding. Bordeaux rejected 60; Lille, 16; Lyons, 63; Montpellier, 46; Nancy, 26; Paris, 386.

Doctor and Preacher.—

Parson and doctor joined in one
Most suitably we find:
The one the suffering body treats,
The other soothes the mind.
The parson shows the way to heaven;
And then, with tender care,
The doctor consummates the work,
And gets the patient there.

—*Medical Age.*

Some Life Statistics.—An eminent statistician of Germany has recently given out the following as general facts, proved by vital statistics: The average length of life is thirty-seven years; twenty five per cent. of mankind dies before attaining the age of seventeen. Of 1,000 persons only 1 reaches the age of one hundred years, and 6 that of sixty-five years; 35,214,000 die every year, 96,480 every day, 4,020 every hour, 67 every minute. The births amount to 36,792,000 every year, 100,800 every day, 4,200 every hour, 70 every minute. Married people live longer than the unmarried, and civilized nations longer than the uncivilized. Tall persons enjoy a greater longevity than small ones. Women have a more favorable chance of life before reaching the fiftieth year than men, but a less favorable one after that period. The proportion of married persons to single is as 75 to 1,000. Persons born in spring have a more robust constitution than those born at any other season. Births and deaths occur more frequently at night than in the daytime.

The Illinois Army and Navy Medical Association held an adjourned meeting at Chicago, October 7th and 8th, at which time the constitution was amended as to eligibility to membership, viz.: "All reputable physicians, whether in practice or not, who served in the Army or Navy during the late war, regardless of the State from which they come, are eligible to membership in this Association." The following resolution was unanimously adopted: "Whereas, in view of our high esteem for Dr. John H. Rauch, as a medical officer of the United States Army during the War of the Rebellion, as a gentleman of worth and culture, and for his most efficient services as a member of the Illinois State Board of Health, and for the untiring energy exhibited as the secretary of said board, whereby the sanitary conditions of the State and nation have been greatly improved, the standard of medical education elevated, and the interests of profession and people most thoroughly guarded; therefore, Resolved, That we hereby express our regret that so efficient a member of the Board of Health of the State of Illinois should have retired from that body. No more efficient, active, earnest worker can be found among the medical profession, to fill that important position, and we believe that the interests of the people, as well as those of the medical profession, will be advanced by his recall to duty thereon." The next meeting of the Association will be held at Vandalia, Ill., at the time of the meeting of the Illinois State Medical Society, but immediately following said meeting.

A Contribution to the Literature of Maternal Impressions.—In an interesting article on "Manners and Customs of Sicily in 1890." by Hamilton Aïdé, in the *Nineteenth Century* for October, 1890, a unique case is mentioned of the family of a dealer in antiquities in Palermo, in which six of the seven children were deaf-mutes. The affliction was on neither side hereditary, both the wife's family and that of the husband being a fine and perfectly sound race. The first child was without blemish; but before the birth of the second, which took place during the Revolution, a bomb-shell burst in the wife's room. The child was born deaf and dumb, and so were the five born subsequently. Four of these children are still living in the Deaf and Dumb Asylum in Palermo.

Hard Metal in Soft Drinks.—During the last quarter the Aberdeen public analyst examined 31 samples of aërated beverages, and only 10 were found to be pure. One quantity of lemonade contained as much as 4.3 grains per gallon of lead, another 2.25, a third 2.25, and a fourth 1.2 grain, while the others contained .90 to .04 grain per gallon. Two samples contained heavy traces of iron, but this impurity is decidedly less objectionable than the other. No wonder lemonade is sometimes contemptuously described as "liquid stomach-ache."—*Medical Press.*

Amateur Surgery.—A writer in the *Hospital Gazette* mentions the following rather curious illustration of the workings of the instinct of self preservation: A boy, while gathering white heather, had the misfortune to be bitten by an adder, and fearing evil consequences from the bite determined to amputate the finger bitten. This he at once essayed to do with his pocket-knife, but having no previous knowledge of anatomy could not get the finger off as he wished. At last he managed to get into the joint, and with a courage that did him credit amputated the finger in a way, and having done so proceeded to a medical practitioner to have the finishing touches put to it. This was done by Dr. Somerville, Galashiels, and so far no evil results have followed the rude operation performed by the adder or the boy.

Women Apothecaries in Russia.—The Russian Ministry of Education has recently sent a circular to all educational and medical commissions of the empire, informing them that every woman who has finished a course of a higher education may be engaged as a pharmaceutical apprentice in a drug store, and, by successive professional examinations, may attain the degree of "provisor," and become a pharmacist with the same rights and privileges as a man.

A Drug Explosion.—A student of pharmacy in Hesse was called upon to put up a prescription containing a twenty per cent. solution of chromic acid, salicylic acid, and water. He put the crystals of chromic acid directly into the alcohol, whereupon an explosion took place, and the unfortunate student was severely burned in the eyes.

Ulceration of the Mouth in Lead-poisoning.—Dr. Osmund Stedman calls attention, in *The Lancet* of September 26, 1891, to the occurrence of ulceration of the mouth in cases of lead-poisoning in children. He had noted several cases in which this was a prominent symptom, and he thinks it well to bear in mind the possibility of such a causation of oral ulcers in children when no other explanation of the condition is evident.

THE SURGICAL TREATMENT OF PYLORIC STENOSIS, WITH A REPORT OF FIFTEEN OPERATIONS FOR THIS CONDITION.[1]

By N. SENN, M.D., PH.D.,

PROFESSOR OF PRACTICE OF SURGERY AND CLINICAL SURGERY IN RUSH MEDICAL COLLEGE; ATTENDING SURGEON TO THE PRESBYTERIAN AND EMERGENCY HOSPITALS; SURGEON IN CHARGE OF ST. JOSEPH'S HOSPITAL, CHICAGO, ILL.

STRICTURE of the pylorus, sufficient in degree to give rise to obstruction, slowly but surely leads to a series of pathological changes incompatible with life, and death from marasmus will eventually result, irrespective of the nature of the primary lesion which caused the stenosis. The progressive narrowing of the lumen of the pylorus causes retention of food in the stomach, which, failing to undergo proper gastric digestion, acts the part of an irritating foreign substance, and in a short time produces a diffuse catarrhal inflammation. The retention in the stomach of imperfectly digested food is followed by fermentation, which still further impairs gastric digestion and adds another causative element in the production of dilatation of the organ. The accumulation of food, and the products of catarrhal inflammation in the stomach, increase as the pyloric outlet of the organ is diminished by the stricture, and dilatation is brought about by the weight of the stomach contents, the weakening of its walls by the secondary catarrhal inflammation, and by the elastic expansion of the organ by the gaseous products of fermentation. In chronic pyloric obstruction I have repeatedly evacuated from the stomach over a gallon of fluid, containing solid particles of food, through an elastic siphon stomach-tube. In one instance fragments of the pulp of an orange were observed in this manner three months after the orange was eaten, showing that when the stenosis has reached a certain stage solid fragments of food may be retained in the stomach, in an undigested state, for weeks and months. In reference to the secondary lesions of the stomach following pyloric stenosis, the train of symptoms is very much the same whether the primary disease is of a benign or malignant nature. Death eventually occurs, not from the disease which has produced the stricture, but from the secondary lesions which develop in consequence of the mechanical obstruction. Irrigation of the stomach, rational use of internal remedies, a carefully selected diet, the use of electricity and massage exert a beneficial influence in the retardation of the secondary lesions caused by the obstruction. They are the most useful means which the modern physician employs in the treatment of such cases to prevent and combat the secondary lesions, but the employment of all these valuable therapeutic resources can at best only postpone, but not obviate, the inevitable fatal termination.

Stricture of the pylorus is a surgical affection, and should be treated as such with the same right and for the same reasons as a stricture of the œsophagus, rectum, or urethra. Reliance on medicine is as deceptive and useless in these cases as in the treatment of stricture of any other organ. Permanent relief can only be secured by prompt surgical interference.

During the last ten years abdominal surgery has widened its field of application and usefulness, and now deals successfully with the surgical affections of every one of the intra-peritoneal organs. Gastric surgery has a short but eventful history. Within a few years hundreds of operations have been performed on the stomach for various indications, and many of them have proved eminently successful. Although the hopes first entertained in reference to the possibilities of extensive resections for malignant disease have not been realized, the results obtained by operative treatment for obstructive lesions have surpassed all expectations, and constitute one of the triumphs of modern surgery. It must not be forgotten that gastric surgery is still in its infancy, and I am quite confident that in less than ten years from now the means for an early accurate diagnosis of the different surgical affections of the stomach will have been so much improved, and the technique of the different operative procedures will have reached such a degree of perfection, that surgeons will then deal with the different localized affections of this organ as successfully as the gynecologist now does with the different affections of the uterus and its appendages. I propose on this occasion to discuss briefly the surgical treatment of pyloric stenosis. I shall divide the subject, in reference to the nature of the obstructive cause, into, 1. Operative Treatment of Cicatricial Stenosis of the Pylorus. 2. Operative Treatment of Carcinoma of the Pylorus. With very few exceptions stricture of the pylorus is caused either by cicatricial contractions following the healing of an ulcer in this locality or a carcinoma. It is very rare indeed to find obstruction here caused by other conditions, such as a non-malignant tumor, congenital stenosis, a twist, or flexion.

1. **Operative Treatment of Cicatricial Stenosis.**—Cicatricial stenosis of the pyloric orifice of the stomach frequently follows as a remote sequela after the healing of an ulcer or traumatic defect in this part of the stomach. The development of the stenosis is a slow process, as it depends upon the formation and contraction of cicatricial tissue which is produced at the site of the former trauma or ulcer. The formation of an excessive amount of granulation tissue in a surface wound or ulcer of the stomach takes place in consequence of the continued irritation caused by the presence of food and digestive fluids, and on this account cicatricial contraction so often follows the healing of a wound of the mucous membrane or ulcer of this organ. A cicatricial stenosis of the pylorus gives rise to symptoms of obstruction at this point—vomiting, retention of food, catarrhal inflammation followed by progressive dilatation of the stomach. Patients suffering from this affection are usually treated for months and years for dyspepsia or indigestion until a careful examination of the stomach reveals the existence of the obstruction and great distention of the stomach, when the diagnosis is often changed to carcinoma of the pylorus. The diagnosis of cicatricial stricture of the pylorus should be based on the clinical history of the case, which usually points to the existence of ulceration months and years before, the use of the siphon, stomach-tube, and inflation. The clinical history usually reveals the existence of disturbed digestion years ago, caused by an unhealed ulcer, and later by the gradually increasing obstruction. For a time the compensatory hypertrophy of the walls of the stomach balances the mechanical difficulties caused by the stricture; but when this is no longer the case, the walls of the stomach become attenuated and dilatation of the organ follows as a constant and inevitable result. At this stage the elastic stomach-

[1] Read at the meeting of the New York State Medical Association, October 28, 1891.

tube is of great diagnostic value. By its use the overloaded stomach is emptied of its contents and the amount of fluid removed often furnishes valuable information regarding the degree of dilatation, while examination of the contents removed often reveals valuable diagnostic points. After the stomach has been thoroughly washed out, its size and location can be accurately outlined by inflation. Even when the stomach is in a normal condition it can be fully distended by inflation from above, and when the pyloric orifice has been diminished in size very little, if any, air passes beyond it when the organ is distended for diagnostic purposes. Air should be forced through the stomach-tube slowly and uninterruptedly from a large rubber balloon, until the contour of the stomach can be outlined on the surface by inspection, palpation, and percussion, which will accurately indicate its size; but this method of examination will also determine accurately its anatomical location and relation to surrounding organs. When the dilatation is very marked, it is not uncommon to find the axis of the organ changed from horizontal to a nearly perpendicular line, and in such cases the great curvature is often found in the left iliac fossa.

The absence of a tumor in the pyloric region speaks in favor of a cicatricial stenosis, but does not preclude the possible existence of an annular malignant stricture. A cicatricial stricture of the pylorus is almost certain to lead to a fatal termination in from three to four years from marasmus, unless the mechanical obstruction is remedied by surgical interference, as a stricture in this locality always manifests an intrinsic tendency to progressive contraction, and finally completely interrupts the entrance of food from the stomach into the intestines. The operative treatment of a cicatricial stricture at the pyloric end of the stomach consists in pylorectomy, digital divulsion of the stricture through a wound in the stomach, in the formation of a partly new pylorus by the pyloro-plastic operation of Heineke-Mikulicz, or, in establishing a new outlet from the stomach into the upper portion of the small intestine by making a gastro-enterostomy.

Pylorectomy.—The mortality of pylorectomy, even in the treatment of cicatricial stenosis, has been so great—about fifty per cent.—while the less heroic procedures have yielded equally satisfactory functional results, that we may take it for granted that this operation will be abandoned in the treatment of this form of pyloric obstruction.

Digital Divulsion of Cicatricial Strictures of Pyloric Orifice of Stomach.—In 1883 Loreta, of Bologna, introduced a new method of treating non-malignant strictures of the pylorus, and later published a number of successful cases. The operation devised by him consists in opening the stomach a little nearer the pyloric than the cardiac extremity, and passing first the right index-finger through the strictured portion, and later also the left, and then separating them, as he did in the first case more than three inches. Considerable force is usually required in dilating the stricture to this extent, and during such forcible stretching there is always danger of tearing through the entire thickness of the wall of the pylorus. The wound in the stomach is closed in the same manner as after gastrotomy for other purposes. The stomach should be thoroughly emptied by irrigation with a mild antiseptic solution before the operation, and during the stretching process the visceral wound should be drawn well into the abdominal incision.

To the immediate risks of Loreta's operation, rupture of the pylorus and dangerous hemorrhage, must be added recurrence of the stricture, which is certainly one of the common remoter consequences following treatment of cicatricial strictures by rapid dilatation wherever the stricture may be located. In this particular it can hardly be assumed that stricture of the pylorus constitutes the only exception. Notwithstanding that a number of successful operations of this kind have been reported, and the operation is being strongly urged by a number of able surgeons, notably by Barton, of Philadelphia, it will undoubtedly never be forgotten, as it is really more dangerous and uncertain in its results than the pyloroplastic operation of Heineke-Mikulicz, which for many reasons is sure to take the place of all other operations in the surgical treatment of non-malignant strictures of the pylorus.

Pyloroplasty.—The safest, and functionally most efficient, operation for cicatricial stenosis of the pylorus is the one devised by Heineke and Mikulicz nearly at the same time. It is a procedure which well deserves the name it bears—pyloroplasty, as it not only removes the mechanical obstruction, but, at the same time, creates a new pylorus. This operation was first planned and practised by Heineke, of Erlangen, and eleven months later Mikulicz, ignorant of Heineke's work, made the operation in exactly the same manner. The operation is made by cutting the anterior wall of the strictured pylorus, and extending the incision about an inch toward the stomach, and the same distance in the direction of the duodenum. The straight incision in the long axis of the pylorus divides the stricture, and the contracted pylorus becomes the posterior wall of the new pylorus by retracting the margins of the wound on each side, at the centre, with tenacula, and suturing the wound in an opposite direction to the incision, that is, transversely to the long axis of the stomach. The new pylorus is made up of tissue, taken partly from the anterior wall of the stomach and partly from the duodenum, the posterior wall being composed of the narrow, contracted pylorus. In suturing the wound it is advisable to tie the sutures from each angle of the wound, tying the central sutures last. Two rows of sutures, deep and superficial, are employed, the same as in closing a wound of the stomach or intestines. Recurrence of the stricture is a physical impossibility, as the new pylorus is composed mostly of healthy tissue, and the danger attending the operation is not greater than that which accompanies an ordinary intentional wound of the stomach or intestines. The results of this operation, obtained in eight cases which have so far been reported, have been very satisfactory both in reference to the immediate effects of the operation and the functional results. In this connection I will give the details of two cases of cicatricial stenosis of the pylorus, in which I employed this procedure, and in both instances with most gratifying results.

Case I. *Cicatricial Stenosis of Pylorus—Pyloroplasty—Recovery.*—An account of this case was published by Dr. F. J. Groner, of Big Rapids, the attending physician, in *The Physician and Surgeon*, March, 1890. The patient was the Reverend Mother Superior of the Convent of Mercy, Big Rapids, Mich., aged forty-seven. General health good until the early part of the winter of 1888, when she began to suffer with symptoms which suggested the existence of pyloric obstruction. The usual treatment for indigestion proved of no avail. Vomiting at variable periods after eating was a conspicuous symptom, and was always followed by relief. On one occasion meat eaten one hundred hours before was recognized in the vomited matter. Vomiting commenced in March, 1889. The symptoms became greatly aggravated during the month of June. The use of the stomach-tube afforded great relief. In the latter part of May the patient consulted me, at the request of her attending physician, and from the clinical history and the symptoms then present, I had no hesitation in corroborating the diagnosis previously made by Dr. Groner—cicatricial pyloric stenosis.

The obstruction evidently became rapidly aggravated, so that even liquids were no longer retained in the stomach. The patient's normal weight was one hundred and ninety-nine pounds, of which she lost fifty pounds during her illness.

The operation was performed, July 16, 1889, at the Mercy Hospital, Big Rapids, Mich. I was ably assisted by Drs. Groner, Barth, Burkart, and Bigelow. The pa-

tient was thoroughly prepared for the operation by washing out the stomach with Thiersch's solution. Chloroform was used as an anæsthetic. The great thickness of the abdominal wall made it somewhat difficult to bring the pyloric end of the stomach well forward into the wound. The pylorus was a circular mass of cicatrical tissue, its lumen not much larger than an ordinary lead-pencil. The incision was carried well toward the stomach and duodenum, in order to obtain sufficient healthy tissue for the new pylorus. The longitudinal wound was transformed into a transverse wound, and united by two rows of fine silk sutures. The lumen of the new pylorus was large enough to admit two fingers. She vomited several times after the operation, but this the patient attributed to the morphia which was administered. For twenty-four hours the stomach was kept perfectly empty. After this time liquid food was administered in small quantities at short intervals. No further untoward symptoms occurred, and the external incision healed by primary intention. Six weeks after the operation the patient resumed her ordinary duties, which consisted of superintending three schools, each fifty miles apart, and the trying task of presiding over two hospitals. Appetite and digestion at this time were perfect. The overwork brought on severe and obstinate attacks of intercostal neuralgia, which required morphine to relieve the pain. This late complication retarded materially the final complete recovery. In December the patient was in perfect health and had regained her former weight. At present there are no indications of recurrence of gastric disturbance, and the patient continues her arduous work with the same energy and efficiency as before her illness. It is noteworthy to state that in this case the patient does not recall any symptoms which would indicate the existence of an ulcer of the pylorus at any time before the last illness, and yet it is almost certain that, probably years before, she was the subject of an extensive circular ulcer at or near the pyloric orifice. The stomach was only moderately dilated, and the walls, if anything, were thicker than in a normal condition. It is evident that the obstruction had existed for a long time, and had resulted in a compensatory hypertrophy of the coats of the stomach, and that at the time of operation dilatation of the stomach and attenuation of its walls were progressing hand in hand. I have no doubt that a few months later both of these conditions would have been greatly aggravated. A timely resort to operative treatment in this case prevented the full development of the remote secondary lesions following pyloric obstruction, and thus averted the serious organic changes which characterize pyloric obstruction of long standing, and which, under these circumstances, often never completely disappear, even after the stricture has been removed by operative treatment.

Case II. *Cicatricial Stenosis of Pylorus following Recent Extensive Ulceration—Pyloroplasty without Anæsthesia—Recovery.*—The second case of pyloroplasty was a Norwegian farmer, fifty-one years of age, who was brought to the Presbyterian Hospital, in Chicago, by Dr. Boeckmann, of St. Paul, Minn., July 5, 1891. No hereditary tendency to carcinoma in his family. He states that he has been a confirmed dyspeptic for twenty years. Eight months before his admission into the hospital he suffered great pain in his stomach, which was always aggravated after meals. The pain was associated with a burning, scalding sensation in the stomach, which was most distressing several hours after meals. About this time the patient had an attack of profuse hæmatemesis which almost proved fatal. The diagnosis made at this time was ulcer of the stomach. By restriction of diet, and occasional use of stomach siphon-tube he obtained temporary relief; but for the last two months he has vomited repeatedly, usually some time after eating. At the time of admission the patient presented an anæmic appearance and was greatly emaciated. No tumor could be detected in the region of the pylorus. Chemical examination of the contents of the stomach revealed the presence of hydrochloric acid. By use of the elastic tube it was ascertained that the stomach held at least twice as much fluid as in a normal condition. From the history of the case, and the symptoms and signs presented, I was ready to endorse the diagnosis of cicatricial stenosis of the pylorus, previously made by the attending physician. As the patient was very much debilitated, his pulse intermittent and irregular, I agreed with Dr. Boeckmann that it would be unsafe to administer an anæsthetic, and that if the patient's consent could be obtained it would be advisable to operate without anæsthesia. The patient readily agreed to our advice, and heroically submitted to the somewhat prolonged operation, responding to questions, and describing his sensations during its progress. As in the former case, the stomach was thoroughly washed out with a weak antiseptic solution just before the operation was commenced. The operation was performed on the same day he reached the hospital. The external incision was made through the median line, from the ensiform cartilage to the umbilicus. According to the patient's own statements this step of the operation caused the severest pain. The incision in the stomach and suturing of the visceral wound produced but little suffering. The stomach was found greatly dilated, its walls very vascular and considerably attenuated. The pylorus occupied its normal location, and presented, anteriorly, a tortuous and twisted appearance. The anterior wall presented otherwise a normal appearance. Digital exploration revealed a hard cicatricial mass, involving the posterior and upper part of the pylorus. An incision about two inches in length was made, parallel to the long axis of the stomach, with the strictured portion as the central point. Inspection and digital exploration now revealed a cicatricial mass posteriorly and above the incision, involving about two-thirds of the circumference of the pylorus, the lumen of which was contracted down to the size of a lead-pencil, and very much distorted. The visceral wound was treated in the same manner as in the foregoing case. Aseptic gauze was packed around the pylorus, and was kept in place from the time this part of the stomach was brought forward into the wound until the suturing of the visceral incision was completed. During the operation the patient complained of nausea, at the same time violent contractions of the stomach were observed, but vomiting did not ensue. The abdominal incision was closed by buried and superficial sutures. The operation lasted nearly an hour, and after its completion the patient was somewhat paler, but expressed himself as satisfied that the pain inflicted was not as severe as he had expected. Rectal alimentation was relied upon for three days, after which stomach feeding was resumed. The diet for a number of days was limited to liquid articles of food. The highest temperature observed was 99¾° F. The wound healed by primary union, and the patient left the hospital much improved in health at the end of twenty-five days. On several occasions the stomach-tube had to be used after the patient commenced to take liberal quantities of solid food, as digestion appeared to be somewhat impaired. I received a letter from him two months after leaving the hospital, in which he informed me that he had gained twenty-seven pounds in weight, and was able to digest all kinds of food without experiencing any distress. Only on a few occasions was the stomach washed out after he left the hospital, for fear that undigested food might aggravate the enfeebled condition of the stomach. As I have not heard from the patient since, I have every reason to believe that he has been free from a relapse. The points of interest in this case are the sex and age of the patient, the short time that elapsed since the ulcer formed and symptoms of obstruction appeared, the almost complete impenetrability of the pylorus by a cicatrix involving only two-thirds of its circumference, and the fact that the operation was performed without the use of an anæsthetic. The com-

plete impenetrability of the pylorus in this case was at least in part due to the tortuous course of its lumen.

The results obtained in the above cases, as well as a study of the literature on the different methods of operative treatment of pyloric stenosis, have led me to the conclusion that pyloroplasty is the safest and most successful operation in all cases in which pyloric obstruction is caused by cicatricial contraction. Pylorectomy in such cases is too dangerous an operation, and even if it should prove successful would not yield as satisfactory functional results as the simpler and safer procedure of pyloroplasty. Digital divulsion of the stricture has been followed by a much larger mortality than pyloroplasty, and the remote danger of recurrence of the stricture, for obvious reasons, is much greater than in the latter operation. Gastro-enterostomy is attended by as much, if not more, immediate risk to life than pyloroplasty, and the functional results can certainly not be as satisfactory as after pyloroplasty, because an important segment of the small intestines is permanently excluded by the operation from the process of digestion. As in the treatment of all other surgical affections of the gastro-intestinal canal, it is important, in order to secure good results, to operate early, before the obstruction has resulted in incurable secondary lesions, it is also important that an early diagnosis of the existence of pyloric obstruction should be made. For practical purposes it is immaterial to make a positive differential diagnosis between benign and malignant obstructive lesions before the abdomen is opened, as in either case operative treatment of the obstruction is urgently indicated. The existence of pyloric obstruction can be ascertained, with a reasonable degree of certainty, by the complexus of clinical symptoms which attends this condition, and the diagnostic tests which demonstrate the increased capacity of the stomach and dilatation of this organ, in reference to the presence or absence of hydrochloric acid in the secretions of the stomach as a test in the differential diagnosis between benign and malignant affection of the stomach and pylorus. Kinnicutt summarizes the results of his investigations as follows :

"The concensus of experience among clinical observers in various parts of the world is to the effect that free hydrochloric acid may be, and is, absent temporarily or otherwise in many gastric affections ; that it is absent in a very large proportion of cases of cancer of the stomach ; that its continuous presence is a diagnostic sign of great value in excluding the probable existence of gastric cancer."

Malignant Stenosis of Pylorus.—Myofibroma and other benign tumors of the stomach are extremely rare, and when present seldom necessitate surgical treatment. Sarcoma of the stomach, as compared with carcinoma, is so very rare that it is only necessary to speak briefly of carcinoma as a cause of pyloric obstruction in the consideration of malignant stenosis in this part of the stomach. It appears that in the stomach the general law is also observed that carcinoma develops in preference where two types of epithelial cells meet. It is a well-known clinical and pathological fact that in the stomach the disease has its primary starting-point most frequently at the pyloric or cardiac orifice, and of these two localities the pyloric is, by far, the most frequently affected. Carcinoma of the pylorus gives rise to many symptoms which suggest the existence of ulcer and cicatricial stricture. This is more especially the case in circular carcinoma, which produces obstruction quite early by infiltration of the tissues and cicatricial contraction. As soon as the internal surface of the carcinoma ulcerates, hemorrhage into the stomach is of frequent occurrence. It is not always easy, or even possible, to ascertain the existence or exact location of a carcinoma of the pylorus by any of the known physical signs or chemical tests. A circular carcinoma of the pylorus may cause death before its presence can be recognized by any known methods of physical examination. An infiltrating carcinoma of the pyloric extremity of the stomach may cause thickening of the walls of the stomach over a large area, and yet it may elude the most painstaking examination if physical signs are relied upon exclusively. In the majority of advanced cases of pyloric carcinoma, however, a distinct tumor can be felt in the pyloric region ; but often the weight of the tumor has carried that part of the stomach in a downward direction, and then the tumor may be found as low down as the level of the umbilicus. Circular carcinoma of the pylorus often causes enormous distention of the stomach, the large curvature of which often reaches as far as the pubes. In such cases the stomach is often placed in almost a vertical position—a condition which greatly aggravates the existing obstruction. It is often very difficult to differentiate between a carcinoma of the pylorus and a retro-peritoneal tumor in the same locality. Inflation of the stomach is the most reliable diagnostic procedure in such cases.

If the tumor is retro-peritoneal it becomes covered by the distended stomach during the inflation ; the previous area of dulness disappears as the tumor becomes covered by the distended tympanitic stomach. If, on the other hand, the tumor is connected with the stomach, its relative position to the anterior abdominal wall is not changed by the inflation. A carcinoma of the pylorus may be suspected if a patient more than forty years of age gives a history of disturbed digestion dating back for several months or a year, combined with evidences pointing to pyloric stenosis. The chemical examination of the contents of the stomach for free hydrochloric acid, so much relied upon during the last few years in making a differential diagnosis between benign and malignant affections of this organ, has been found a valuable aid, but the results thus far obtained are not infallible. Hæmatemesis in persons beyond middle age, progressive marasmus, and enlargement of the cervical glands speak in favor of malignant disease. The surgical treatment of pyloric carcinoma consists either in removal of the diseased part by pylorectomy, or the formation of a new outlet from the stomach into the upper portion of the small intestines by gastro-enterostomy.

Pylorectomy.—A limited carcinoma of the pylorus, if it has not resulted in extension of the disease to adjacent organs or infiltration of the lymphatic glands behind it, furnishes a legitimate indication for a radical operation. If, however, the disease has extended beyond the walls of the stomach, pylorectomy is contra-indicated and the surgeon must be content to render the obstruction harmless by establishing a new route by which the contents of the stomach can reach the intestinal canal. If the patient objects to an operation life can be greatly prolonged and a great deal of suffering prevented by placing the patient on a carefully selected diet and by resorting to irrigation of the stomach as often as the retention of the undigested food may render this procedure necessary. Pylorectomy has so far not yielded results which would encourage surgeons to have more frequent recourse to it in the treatment of malignant stenosis. The great mortality of this operation and early relapses are easily explained by the fact that heretofore operations were usually performed after the patient's strength had been greatly reduced by the disease and after extension of the disease to the surrounding organs or lymphatic glands had taken place. Statistics appear to show that the results have not improved much during the last few years. At the Berlin International Medical Congress (1890) Billroth gave an account of 27 pylorectomies, all of which were performed either by himself or his assistants. Of this number 12 recovered from the operation and 15 died. Of 13 pylorectomies for carcinoma which survived the operation, 5 died after ten months, and 1 after five years and three months after the operation from recurrence. There were yet living three women at the time the report was made, of whom two had been operated upon two and one-half and four and one-

fourth months. Of 6 resections of the pylorus for cicatricial stenosis 3 recovered. These results, obtained by the ablest of living surgeons, certainly leave much to be desired, and cannot fail in influencing surgeons to limit the sphere of the operation to favorable cases. The proper time for pylorectomy will come when we shall be able to recognize carcinoma of the pylorus during its incipiency, at a time when the patient's general condition is such as to be able to resist the immediate effects of the operation; when this time has come the mortality will be small and the relapses few. At present it seems to me that the operation is only justifiable where the patient's strength is fair and where the disease is limited and has not passed beyond the organ primarily affected.

Gastro-enterostomy.—Gastro-enterostomy is an operation by which an anastomotic communication is established between the stomach and the upper portion of the intestinal canal, with exclusion of the duodenum and sometimes a portion of the jejunum. This operation is performed as a curative or palliative measure in cases of pyloric obstruction when removal of the cause of obstruction is impossible or not advisable. This operation was devised and first practised by Wölfler. Wölfler made an incision about three inches in length in the anterior wall of the stomach, at a safe distance from the carcinoma and near the great curvature, and a similar incision in the convex side of the intestine about thirty inches below the plica duodeno-jejunalis, and united these two visceral wounds with sutures, thus establishing a direct communication between the stomach above and the small intestines below the obstruction. In uniting the posterior margins of the wounds the serous or superficial sutures should be first inserted, and tied when the inner or second row are tied, and cut short to the knot. Silk should be used exclusively as suturing material. In Wölfler's operation the current of the intestinal contents is in a direction opposite to the peristaltic action of the stomach, a condition which necessarily must be unfavorable to the easy escape of the stomach contents into the intestinal canal, a circumstance which led Rockwitz to so modify the operation that he turns the intestinal loop one-half around its axis and unites the intestine with the stomach in this position, and thus brings the two organs in such relative position that the peristaltic action of both takes place in the same direction. Von Hueker has modified the operation still further and establishes the communicating opening in the posterior instead of the anterior wall of the stomach. The portion of intestine which should be united with the stomach is a point about twenty-four to thirty inches below the pylorus.

Operators have experienced a great deal of difficulty in finding this place without too great loss of time and unnecessary and harmful handling of the intestines. Luecke gave the advice to seize and unite with the stomach the first intestinal loop that presents itself in the external median incision, and gave it as his opinion and the result of his experience that in doing so the anastomotic opening will invariably be made near the desirable point, not distant from the duodenum. This advice has led to serious mistakes. In one of the writer's cases, in which this direction was followed, the autopsy revealed the fact that the opening had been made eight feet below the pylorus, and in one of Lunenstein's cases the opening was found near the ileo-cæcal region, consequently nearly the entire length of the small intestines had been excluded from participation in the progress of digestion and absorption. In searching for the upper portion of the small intestines it is not always easy, as has been claimed by Hahn and Kënig, to find the plica duodeno-jejunalis, and as the result of quite an extensive experience the writer recommends the following plan: The first loop that presents itself is brought forward into the wound and is held in this position by an assistant, while the surgeon follows the ntestine in one direction, observing carefully its color nd the thickness of its walls as loop after loop is examined. If the intestine leads in an upward direction the color becomes paler and the walls thicker, and the duodenum will soon be reached. If he is tracing the bowel in an opposite direction the intestine becomes gradually smaller, its walls thinner, and the color more of a bright red hue. Should this be the case the loops of the intestine are returned, and the examination is made from the loop held by the assistant, in an opposite direction, which will soon lead to the part that it is intended to unite with the stomach. As soon as the desired loop is reached it should be twisted around, as advised by Rockwitz, and held in this position by an assistant until the anastomosis has been completed. Of 21 gastro-enterostomies collected by Rockwitz, made for malignant and cicatricial stenosis of the pylorus, the mortality is represented by 57.2 per cent. Billroth reports 28 operations for malignant pyloric stenosis, with 14 deaths. Of those that survived the operation all died in from one to eight months. This great mortality is due to the debilitated condition of the patients operated on, and the great length of time required in uniting the visceral wounds by suturing. Gastro-enterostomy, as heretofore described and performed, is an operation attended by many difficulties, and requires, even in the hands of an expert, an hour or more for its execution.

As this operation is only done in cases greatly debilitated by disease and long-suffering, anything which will simplify the technique and shorten the time must be looked upon as an improvement. An operation that can be done in ten or fifteen minutes, instead of an hour or two, and which furnishes much better conditions for the healing together of the margins of the visceral wounds, must take the place of the more complicated procedures, which so far have only been practised in the hands of the most experienced surgeons. The author has modified Wölfler's operation by securing opposition between the stomach and the intestine by means of perforated decalcified bone-plates, a method which greatly shortens the operation and brings the parts in a more favorable condition for speedy union. The approximation-plates are reinforced by a number of superficial sutures in the same manner as in establishing an intestinal anastomosis. Scarification of the serous surfaces included by the plates will greatly hasten the formation of firm adhesions and expedite the process of healing by granulation. As the mucous membrane of the stomach always shows a great tendency to evert, it should be fastened in the middle of the wound with a fine catgut suture before the wounds are approximated. A gastro-enterostomy, with the aid of approximation-plates, can be completed in from fifteen minutes to half an hour; while, if suturing is relied upon exclusively, the time required cannot fall much short of an hour and a half.

The following experiments of the author, taken from my work on "Intestinal Surgery," are well calculated to illustrate some of the advantages attending the use of absorbable approximation-plates over the ordinary methods of suturing in gastro-enterostomy:

Experiment 1.—Dog, weight twenty-five pounds. Incision made through linea alba, from xiphoid cartilage to near umbilicus. Omentum pushed to one side, and the stomach drawn forward into the wound; near the middle of its anterior surface a longitudinal incision was made, two inches in length, and a gutta-percha plate with a central oval opening the size of the pyloric orifice was introduced. Four medium-sized juniper catgut sutures were attached through small perforations around the opening, one at each end and one on each side. The lateral sutures, armed with needles, were passed through the entire thickness of the walls of the stomach, half-way between the angles of the wound. A similar incision was made into the intestine at the junction of the duodenum with the jejunum; the same kind of plate introduced, and the margins of the wound punctured by the lateral armed sutures, when the two wounds were brought *vis-à-vis* and the corresponding sutures tied. In

tying the sutures, the lower lateral suture was tied first and the threads cut short; next the sutures corresponding to each angle of the wound were tied, and lastly the upper lateral. The serous surfaces of the stomach and intestine over an area corresponding to the size of the plates were brought into accurate permanent contact by the tying of the sutures. The stomach was replaced and the abdominal wound closed. The animal was allowed to eat immediately after the operation, manifested no signs of illness or pain, and was killed seven days after operation. Abdominal wound healed. Omentum adherent to its inner surface. Union between stomach and bowel firm over the entire surface of approximation. Plates detached, the one in the bowel had passed, while the other was found loose in the stomach. The new opening was large enough to admit the index-finger.

Experiment 2.—Dog, weight fifty pounds. The operation was performed in the same manner as in the previous experiment, but great difficulty was experienced in bringing the stomach forward, as this organ was distended to its utmost with an enormous quantity of solid food. Evacuation was effected through the incision, aided by attempts of the animal to vomit, the violent contractions of the stomach forcing the food toward the opening, from which it was removed with fingers and spoon. After the stomach was emptied it was washed out with warm water. From the stomach a bone-plate, only partially decalcified, was used, while the approximation-plate in the bowel was fully decalcified. The four approximation sutures were of catgut. Several portions of omentum, which were soiled during the emptying of the stomach, were excised. The abdominal cavity was thoroughly irrigated with warm water before the wound was closed. The animal died the next day, and on opening the abdomen it was ascertained that the immediate cause of death was hemorrhage, as the peritoneal cavity was filled with blood. The bleeding undoubtedly took place from the omentum, by slipping or loosening of one of the catgut ligatures.

Experiment 3. — Medium-sized dog. Operation performed in the same manner with decalcified bone-plates and catgut sutures. The first two days the animal had several attacks of vomiting; it subsequently showed no signs of suffering. Appetite good and stools regular. Killed thirty-four days after operation. Omentum adherent to inner surface of abdominal wound. At point of operation stomach was contracted, so that the organ presented an hour-glass appearance. Interior of the organ contained a large mass of hay and fragments of bone. New opening large enough to pass index-finger. Union between stomach and bowel over entire surface of approximation. Water passed into the stomach flowed through the pyloric orifice and the new opening in a stream of equal size.

Experiment 4.—Large bull-dog. Approximation of anterior surface of stomach with bowel by perforated gutta-percha plates, and four catgut sutures. Length of visceral incisions, two inches. The day after operation the animal vomited his dinner; subsequently no unfavorable symptoms. Killed fourteen days after operation. Abdominal wound well united. Omentum adherent to wound, duodenum, liver, and at the point of operation. Firm adhesion between stomach and bowel. Water admitted into the stomach only passed through the pyloric orifice. On opening the stomach it was found that the wound in the stomach and intestine had completely healed, the site of incisions being marked by a narrow, firm cicatrix. The failure of obtaining an anastomotic opening between the stomach and intestine could only be attributed to one of two causes, viz.: either the perforations in the plates were too narrow, or the needles of the lateral sutures included too much tissue. Either cause would bring about approximation of the margin of the wounds and permanent closure of the opening by granulation and cicatrization.

Remarks.—All of the animals recovered, except in case of Experiment 2, without any untoward symptoms, although they were allowed to eat immediately after the operation, and the diet was not selected or restricted at any time. In the fatal case death was caused from complications which had no connection with the gastro-intestinal opening. In all of the specimens examined, the mucous membrane of the stomach and intestine which had been interposed between the approximation plates, presented a healthy appearance, showing that the pressure of the plates had exercised no injurious effect on this structure. More recent experience with this operation on animals has revealed the fact that in the stomach a completely decalcified bone plate is almost entirely digested in thirty-six to forty-eight hours. It would therefore appear advisable to use only partially decalcified bone, which remains for a longer time, so that in case of delayed union the approximation would be maintained for a sufficient length of time. As the animals subjected to the operation recovered promptly, and under the most unfavorable conditions, we have every reason to believe that this operation will be attended by the same favorable results when done for pyloric or duodenal stenosis in man, where a careful preparatory and after treatment cannot fail to facilitate the operation and to improve the conditions for the formation of early adhesions and a speedy definitive healing of the wound. I have no hesitation in recommending it as a substitute for the more time-consuming and less certain operation by the tedious and difficult method of double suturing which is now generally practised.

Gastro-Enterostomy by the Aid of Absorbable Approximation Plates.—*Preparation for Operation.*—The patient must be placed on a restricted diet for a number of days, and during this time the bowels should be evacuated freely by saline cathartics. If the stomach is much dilated it should be evacuated and washed out daily with an aqueous saturated solution of salicylic acid or Thiersch's solution. Irrigation of the stomach immediately before the anæsthetic is administered should never be neglected. The abdomen and anterior surface of the chest should be scrubbed with warm water and potash soap, shaved, and then washed with sulphuric ether or equal parts of turpentine and alcohol for the purpose of removing the fatty material and more effectually disinfecting the glandular appendages of the skin, and the umbilical depression. A compress saturated with a 1 to 2,000 solution of corrosive sublimate is now applied over the field of operation, which is then covered with an impermeable covering, such as gutta-percha tissue or oiled silk, and kept in place by a circular bandage, or a broad, snugly applied binder. If no contra-indication exists, chloroform is preferable to ether as an anæsthetic, as it is less liable to produce vomiting, an occurrence which should be guarded against as far as possible in this operation. If the patient is weak, two ounces of whiskey in a cupful of warm water should be administered per rectum just before the anæsthetic is administered.

Incision.—A straight median incision, extending from the ensiform cartilage to the umbilicus, will afford ample room to bring well forward into the wound the pyloric end of the stomach, and the loop of intestine which is to be united with the anterior surface of the stomach. The fastening of two or more catch-forceps to the parietal peritoneum on each side of the wound will facilitate the remaining steps of the operation. Hemorrhage must be carefully arrested by applying a sufficient number of hæmostatic forceps before the peritoneal cavity is opened.

Decalcified Bone Plates.—The material used for approximation plates should be such as to resist the action of the gastric and intestinal juices, and secure efficient mechanical support for at least three or four days. Plates are much better than rings, because they coaptate and hold in accurate contact larger surfaces of the peritoneum and at the same time act as splints, securing for the

parts interposed between them complete rest. After having used many kinds of material for this purpose I settled on using decalcified bone exclusively. This substance will give the desired mechanical support for a sufficient length of time, when it is absorbed or disintegrated and disappears spontaneously, and there is no risk of a foreign body being left in the stomach as an irritant and perhaps later on as a cause of intestinal obstruction. The mishaps in the use of plates that have happened in my practice have been all in the use of dried plates. I consider the use of all hygroscopic material for the plates as dangerous, as the swelling of the plates may cause extensive pressure necrosis. The plates are now kept in a solution of equal parts of alcohol, glycerine, and water, between two pieces of glass, so as to preserve their smooth surfaces and prevent warping. The fixation sutures should be medium-sized silk, as cat-gut sutures are not sufficiently reliable, the knot is liable to become loosened and slip, and this material, when exposed to the action of the gastric and intestinal juices, does not resist their destructive action for a sufficient length of time. I must continue to insist that the sutures should be fastened to the plates by the single stitch, as if anything should happen to the plate before adhesions have formed the sutures will still continue to hold the parts in apposition. The retention of the lateral or fixation sutures in the margins of the wound for weeks or even months is of no consequence, as I have seen the same repeatedly after circular resection of the intestine without any harm resulting from it. Eventually the threads will work their way through the tissues and escape. The size of the plate, and especially of the oval central opening of the plate, should be sufficiently large to insure a permanent opening in the stomach at least as large as the lumen of the normal pylorus. The perforation in the centre should be at least an inch and three-quarters in length and about half as wide. The margin of the plate around the oval opening should be from one-third to one-half an inch in width. In using plates of this size and with such large openings there is no danger of not obtaining a sufficiently large anastomotic opening which, when once formed and lined with mucous membrane, will not undergo cicatricial contraction.

Approximation of Visceral Wounds.—It has already been stated that the most desirable point for making the opening in the small intestine is about thirty inches below the obstruction. How this part of the bowel can be formed most speedily, safely, and with the greatest degree of certainty has already been described. As soon as the abdomen has been opened the great omentum should be pushed aside and the intestinal loop selected brought out at the lower angle of the incision. The direction of the bowel must be ascertained and then the loop brought into the position recommended by Rockwitz and entrusted to a reliable assistant, who should have sole charge of it until it has been united with the stomach.

The intestinal loop is surrounded with a compress of aseptic gauze, when an incision long enough to introduce the bone-plate edgewise is made in the concave side directly opposite the attachment of the mesentery. After the bone-plate has been properly adjusted the lateral or fixation sutures are passed through the margins of the wound equidistant from the angles and only enough tissue is included to hold the plates in place after the organs have been approximated by tying of the sutures. It is a good plan to direct the needles obliquely, from within outward, and to embrace all of the tissues with the exception of the peritoneum. While the stomach is subjected to the same treatment the intestinal loop is held as before. The opening in the bowel is covered with loose gauze, so as to absorb what little might escape from the interior of the intestine, which, under such circumstances, is usually nearly, if not completely, empty. As the stomach is usually more or less dilated, it can be found without any difficulty. The pyloric portion is brought forward into the wound and is surrounded with a compress of gauze wrung out of warm sterilized water. The opening is made in the anterior wall, near the great curvature, parallel to the long axis of the organ, and at least two inches from the border of the carcinoma. As the mucous membrane always bulges outward and the wound sometimes bleeds freely, both of these conditions are corrected by a few stitches of the continued suture with fine catgut. No force should be used in inserting the bone-plate, the incision should be sufficiently long to permit its easy insertion. After the plate has been properly adjusted and fixed by the lateral sutures and the serous surfaces which it is intended to bring into apposition by the plates are scarified, the two wounds are brought directly opposite each other and the approximation commenced by tying the posterior pair of lateral sutures; the threads are cut short to the knot. The sutures must be tied only with sufficient firmness to bring the parts into apposition without endangering the circulation. Next the end sutures are tied and lastly the anterior pair of lateral sutures. Before these are tied the margins of the wound in the stomach and bowel must be carefully pushed between the plate with a director or probe. The knots of the lateral sutures should be buried as deeply as possible, which can be done best with a probe or a pair of small, blunt-pointed scissors. It is advisable to support the action of the plates by a few superficial stitches of fine silk. On the posterior side these stitches should be inserted and tied before the plate sutures are tied. On the anterior surface approximation of the serous surfaces along the margins of the plates can be accomplished most speedily by a few stitches of the continued suture of the same material. After cleansing and drying the parts which have been exposed during the operation the stomach and with it the attached intestine are returned into the abdominal cavity, and the external wound is closed by a row of buried and superficial sutures. The external wound is either sealed with iodoform collodion, or the customary antiseptic hygroscopic compress is applied and held in place by strips of adhesive plaster.

After-treatment.—Stomach feeding must be postponed until quite firm adhesions have formed between the approximated parts, which will require at least two days. During this time the patient's strength is to be supported by rectal alimentation and thirst is quenched with small fragments of ice or sips of hot water. Anodynes should not be given unless the patient is very restless or suffers a great deal of pain. Should painful distention of the abdomen occur about the second or third day a saline laxative should be administered, and if required its action is assisted by a stimulating copious enema. After the first forty-eight hours small quantities of liquid food at short intervals are allowed, and at the end of the first week the patient is placed on a carefully selected diet, which must be continued until the process of repair between the approximated serous surfaces is completed. Patients should not be allowed to leave the bed for at least four weeks, as otherwise a ventral hernia at the site of incision is very prone to appear as one of the remote consequences of the operation.

(To be continued.)

Cleansing of the Hands after the Use of Carbolic Acid or Corrosive Sublimate.—Carbolic acid is removed from the hands by bathing them for a sufficient time in alcohol and then anointing them with lanolin. After the use of corrosive sublimate solution the hands should be bathed in a solution of common salt one to fifty, then washed with soap and water, and finally rubbed with lanolin.—*Pharmac. Central.*, No. 28, 1891.

The Influence of Arsenic.—Mr. Hutchinson, of England, has formed an unfavorable opinion as to the influence of arsenic in the treatment of skin diseases of elderly persons, and unless the disease imperatively demands it he never prescribes it for them.

THE ART OF TEACHING MEDICINE.[1]

By STEPHEN SMITH, M.D., LL.D.,

PRESIDENT OF THE NEW YORK STATE MEDICAL ASSOCIATION.

THE Father of Medicine has been represented to us by an eloquent writer in the attitude of a teacher. He says: "Near a column of the temple, and holding a roll of papyrus in his left hand, stands Hippocrates. Gathering about him in picturesque little groups, there is a company of Greek youths. Their tasteful and elegant costumes, their earnest and intelligent faces, and their general air and bearing all show plainly enough the superior refinement and culture of the class to which they belong. They are medical students who have assembled here from the several states of Greece to acquire the clinical skill and experience of the great surgeon and physician of Cos."

It is not difficult to determine the method of instruction pursued in the school of Cos. Hippocrates was the contemporary of Socrates and Plato, and doubtless adopted the plan of teaching so popular at that period. "The method of instruction which Socrates chiefly made use of," says his biographer, "was to propose a series of questions to the person with whom he conversed, in order to lead him to some unforeseen conclusion. He first gained the assent of his respondent to some obvious truths, and then obliged him to admit others, in consequence of their relation or resemblance to those to which he had already assented. Without making use of any direct argument or persuasion, he chose to lead the person he meant to instruct to deduce the truths of which he wished to convince him, as a necessary consequence, from his own concessions. He commonly conducted these conferences with such address as to conceal his design, till the respondent had advanced too far to recede. On some occasions he made use of ironical language, that vain men might be caught in their own replies, and he compelled them to confess their ignorance. He never assumed the air of a morose and rigid preceptor, but communicated useful instruction with all the ease and pleasantry of polite conversation."

From this description of the method of instruction by the philosophers of that day, we can readily understand the art of teaching in the school of Cos. The temple was that of Æsculapius, and here the sick congregated for treatment, and here were kept the votive tablets, or records of sickness of all who sought medical advice within its precincts. With these patients who daily visited the temple, and the vast collection of records, as materials for study, the professor gathered his class about him and proposed a series of questions to each student; having gained his assent to some obvious truths, he would oblige him to admit others related to, or resembling, those to which he had already assented. In this manner he led the person whom he was instructing to deduce the truths of which he wished to convince him as a consequence of his own concessions. He disciplined certain students, always found in the class, who, owing to their conceit are very forward, and often impertinent, by the use of ironical language, by which they were caught in their replies and compelled to acknowledge their ignorance. This teaching was all done in a most familiar way, with the ease and pleasantry of polite conversation, and not with the morose and rigid air of a preceptor.

Such was the art of teaching medicine at this early period, and we now recognize it among the lost arts. The principle which underlies it is this: There must be such a familiar relation between the teacher and the pupil that the latter is constantly under the immediate and personal superintendence of the former, and instruction is given by mutual questioning and answering. Bacon quaintly, but very truly, remarks: "He that questioneth much shall learn much." This simple axiom embodies the whole art of teaching and of learning. In a scheme of education based on this principle the student is not a passive agent who simply receives what is offered him. On the contrary, he is active and aggressive; he is inquisitive but thoughtful; he is receptive, but only of demonstrated facts. Every step of progress in his studies is taken with precision, and no necessary questions are left unanswered. The student thus trained lays broad and deep the foundations that will insure future success. He will not, for he cannot, be indolent. Habituated to inquire, his mind will never be at rest. If ambitious, he will despise mediocrity and attain to distinction in whatever field he is placed.

In nearly every department of education but medicine the system of instruction is based on the above axiom. The student is placed in a position of constant questioning and being questioned. From the rudiments of each science to its most abstruse problems he has the attitude of an inquirer. The text-books which he studies are little else than questions. The instructor is constantly inviting questions, and answering or explaining doubtful points. The prevailing systems of education require personal contact between teacher and pupil. Every feature of the school is subservient to the one great purpose of facilitating questioning and answering on the part of the student. To that end the building is planned, the furniture selected, the apparatus supplied, the books chosen, and the teachers employed. The student is the unit in this system, and every condition must subserve his interests.

Far different is our system of medical education. The student no longer studies. He "reads" medicine. Two-thirds of the year he idles away his time reading works which have not the slightest adaptation to his wants. He is alone, and hence he asks no questions. There is little in the books to stimulate a solitary student to inquiry. During the remainder of the year he attends lectures in a medical school where his individuality is completely lost. There is no classification of students according to their grade of advancement, but all stand on the same footing and listen to the same lectures. In this common and miscellaneous gathering the student sinks into insignificance, while the professor becomes the most prominent feature of the school.

All the appointments of the college are designed to increase his importance and to facilitate the discharge of his duties as a lecturer. At each lecture the entire body of students assemble; the professor enters with due formality and delivers himself in an oracular manner; he retires, not to be seen again until the next lecture. Sometimes the professor asks a few general questions before his lecture, which one or two of the class always promptly answer. But the remaining students are dumb in the presence of their teacher, and open not their mouths. Occasionally a student of the inquisitive, Baconian type follows the professor to his private quarters, and plies him with questions, but he soon learns that his inquiries are not agreeable, and he ceases to enjoy this small privilege. The professor is the unit of interest in this school.

These facts suggest the question: Should not our system of medical education be placed on the same basis as that which gives so much value to other branches of study? In other words, should not the medical course of instruction be graded, and the medical student be required to pass through these several grades under the immediate instruction and direction of his teacher? We give an emphatic answer in the affirmative. By no other method can justice be done to the student in the present enlarged and exact state of the medical sciences. The primary branches—anatomy, chemistry, and physiology—cannot be more adequately taught by lectures than mathematics, Latin, or Greek. And the same is true of the practical branches—medicine, surgery, and obstetrics. The method of teaching these latter subjects by lectures alone is best illustrated by the saying, that it is learning to swim without going into the water, or becoming a navigator without seeing a ship. Nor should our present methods of giving clinical instruction by lectures be excepted from the general condemnation. The

[1] Address before the New York State Medical Association, October 28, 1891.

student may gain some useful hints from the coarser operations in surgery, and from the exhibition of a few cases of the gross forms of external disease. But how meagre the amount of practical knowledge gained, compared with what he would have acquired had he been brought into personal contact with the subject, and been required to use his own eyes, ears, nose, and fingers under the immediate guidance of a skilful instructor! And how much the amount and value of that knowledge would have been enhanced if he had had the privilege of questioning and being questioned in reference to every doubtful point in his investigation! If the case were one of disease of the heart or lungs in which the diagnosis depended upon an accurate appreciation of a sound, of what immense importance to the student are the immediate and familiar promptings of a teacher! Perhaps at the commencement of the present century, when the medical sciences were comparatively in their infancy, and largely theoretical, teaching by lectures may have been adequate. We have, indeed, a remarkable illustration of this fact in the early history of Dartmouth Medical College. For twelve years Dr. Nathan Smith was the Faculty, and gave all the lectures on all the branches then taught, being at once Professor of Anatomy, Surgery, Chemistry, and the Theory and Practice of Medicine. But what a vast development of the medical sciences has been made during the century! Not only have they been enlarged far beyond the comprehension of the earlier teachers, but they have been perfected in details until many of them may be classed with the exact sciences, while all are complete in terminology and classification. Even the practical branches are becoming less and less theoretical and speculative as investigation by improved means and apparatus daily add new facts and determine doubtful questions.

Medicine having, therefore, assumed the rank and character of the technical sciences, should be taught by the method approved by the best educators. This method has as its basis the gradation of subjects from the rudiments of the science to its most complex forms; classification of students according to their advancement in the course of study; an organization of classes so that every student thoroughly reviews each subject under the immediate supervision of a competent instructor; ample means of illustrating every subject, and of enabling the student personally to learn by practical demonstrations and experiments; the preparation of text-books adapted to this method of instruction.

It is not difficult to outline a medical school which would realize the ideal contemplated in the foregoing sketch.

First, the school should be so located as to have all the necessary conditions for anatomical, chemical, physiological, and clinical demonstration and research; the building should be so constructed that there is an ample supply of class-rooms, each being adapted to the particular branch taught in it. Thus the anatomical room or rooms should have all necessary facilities for dissection; the chemical and physiological rooms equipped for every form of experiment required; the rooms for the practical branches and clinical instruction adapted for their special purposes; a department arranged for post-graduate courses of study; finally, a hall for lectures to the general class or to special classes.

Second, a faculty should be selected composed of one professor for each general branch taught. Each member of the faculty should be the highest authority in his branch obtainable. This faculty should be the governing body, having as duties the supervision of the teaching, the selection of instructors, the final examination of students for graduation, and the delivery of such lectures as may be deemed necessary to supplement the direct instruction of the tutors.

Third, a corps of instructors, selected for their known qualifications to teach the branches to which they are assigned.

Fourth, a division of the students into sections or classes, not to exceed twenty-five in each; the division being based upon a grading of the students according to their proficiency or advancement in each branch of study; to each section an instructor should be assigned who will be immediately responsible to the professor for the thorough training of each member of his class.

The practical operations of the school might be on the following plan: The term should comprise the year, with a short summer vacation, in order that the student may be in continuous training under his instructor. The recitations should be at such intervals as will secure time for preparation. At the recitation each student should receive such an examination as will satisfy his instructor that he thoroughly understands every point in it. Such recitations should be devoted to acquiring exact technical knowledge, and practical demonstrations by the student, under the immediate supervision of his teacher, of every subject which admits of illustration by experiment or any form of manipulation. If the subject is the anatomy of the skeleton, the pupil should demonstrate, with the bones in his hands, each feature of the lesson; if the soft parts are under review, he should show his knowledge by dissection; if the lesson is in chemistry or physiology, he should prove every proposition by experiment; if the studies are clinical, he should personally examine the patient in every detail necessary to a correct diagnosis, and subsequently follow the case to its termination. Whenever a student in any branch appears to the instructor to be thoroughly qualified, he should be examined critically by the professor of that branch or science, and if found qualified, should be duly certified by the professor, and advanced to the next grade of study. Thus he proceeds until he completes the curriculum prescribed, when he receives a final examination by the faculty, and if qualified, graduates.

In a school organized and managed in the manner described, time may be eliminated as a factor to be considered in graduation. Educational qualification alone should determine that question. In such a school, also, the better students can be advanced more rapidly than others less apt in learning, by suitable classification.

Nor are lectures precluded as an element of instruction. On the contrary, lectures by the professors on certain subjects, especially in the practical and clinical parts of the course, would be useful and hence desirable. With the adoption of this system of teaching would follow the necessity of the preparation of a series of text books. Scarcely a work now in the hands of students has that systematic arrangement and treatment of subjects which would adapt it to a completely graded course of medical instruction. Our works on anatomy, physiology, chemistry, and the practical branches are deficient in that orderly development of the sciences which they are designed to teach, and of that clear and precise statement of facts, and logical deductions on which their conclusions are based, which the student requires.

This discussion suggests the pertinent and practical question: Can existing medical schools adopt and successfully manage this scheme of instruction? There would seem to be no feature in the plan which it would prove difficult to realize. Buildings could readily be adapted to teaching by recitations; instructors may be obtained, of the highest order of qualification, in unlimited numbers; each department can be equipped with every necessary appliance for demonstration, experimentation, and illustration; and, finally, suitable text books would, as in the academic schools, soon be amply supplied. But we are not left to conjecture as to the practicability of at once reforming our system of medical education on the basis now proposed. Already one of our largest metropolitan medical schools has adopted the method of instruction by recitations, in what may be called the primary branches, and with gratifying success. Several other medical colleges in different parts of the country have also, in whole or in part, adopted this system with equally good results. These are gratifying indications of a revival of the ancient and true Art of Teaching Medicine.

LEPROSY.

By REV. FRANK VAN ALLEN, M.D.,
MEDICAL MISSIONARY, MADURA CITY, SOUTH INDIA.

It is not the object of this article to enter into a historical sketch of leprosy, but only to say in that connection that the disease which we know as leprosy to-day is without doubt not the leprosy described in the Bible and other ancient writings. The term leprosy, as used in the Bible, certainly included more than one form of skin disease. That disease developed rapidly, important changes taking place in two or three weeks. The disease which we know now as leprosy has a slow development, months and even years passing before notable changes occur. Also, the accounts in the Mosaic writings give no indications of the three characters which may be said to constitute leprosy of the present time : tubercles, anæsthesia, and distortion of parts. Moreover, the most noticeable characteristic of that form—namely, its extreme contagion—is almost absolutely wanting now.

Leprosy, which a few centuries ago, and even a few decades ago, was confined to a few countries, such as the Sandwich Islands, Norway, India, etc., is now, due no doubt to the easy means of communication and travel, becoming a more or less common disease. There are now in the United States three or four centres of it. The first cases of leprosy in each of these places were emigrants from countries where leprosy exists.

There are two forms of this disease, the tubercular form and the anæsthetic form ; to which may be added the mixed form, or the tubercular and the anæsthetic forms occurring together. The latter form is by far the most common.

A case of pure tubercular leprosy presents the following characters : The first evidence of the disease is the appearance of one or more little hard nodules or tubercles of about the size of a pea. These appear in most cases first on the cheeks, chin, nose, or ears. These nodules are slightly tender on pressure, and in Europeans of a dull red color. The skin for some distance about is found to be somewhat thickened. It is probable that this tubercular thickening of the skin precedes in all cases the appearance of the tubercles. At this early stage, and for some time afterward, the general health of the leper is good.

After the first appearance of the thickened skin and tubercles, in which the constitutional symptoms, fever, etc., are slight or unnoticed, there is no apparent progress of the disease for several months or a year, or even longer. Then occurs an outburst of new tubercles, or an increase in size, or ulceration, of the old ones, and the skin seems at the same time to have taken on an increased thickening. This exacerbation is preceded and accompanied by fever, varying in intensity from 101° to 105° F. The latter temperature is most common in the later stages of the disease. There is commonly vomiting and other signs of derangement of the system at these times. These symptoms last from three days to two weeks, after which a period of quiescence supervenes and no advance of the disease is seen. As time goes by these onsets of the disease become more frequent and severe. Tubercles appear on the hands and feet and lower legs. The hands and fingers become thickened and puffy, as also do the feet and the toes, and the nails become scaly and cracked. About this time tubercles may appear also in the throat. The appearance of the face at this later stage is very characteristic—the thickened, lumpy look of the cheeks and chin, the knobbed appearance of the nose, the heavy œdematous ears standing out from the head as if they had been severely frost-bitten, give a look not to be mistaken. At this stage of the disease, and exceptionally in the earlier stages, the tubercles may break down and ulcers be formed. This occurs most commonly on the lower extremities. These ulcers may run into each other and become broad, but are never deep. The ulcers are acute and usually heal up after an exacerbation has passed, but in some few cases continue chronic till the death of the leper.

The general health of the leper, at first good, has begun to suffer after five or eight years' continuation of his disease. He falls into a weak state and very gradually sinks lower and lower with each exacerbation, and finally dies of inanition.

The duration of a case of tubercular leprosy is from twelve to forty years.

A case of pure anæsthetic leprosy presents the following characters : The first evidence of the presence of the disease is the appearance of a patch of hyperæsthesia, usually on the hand or on the foot. These patches have a burning sensation, more or less marked, and in size may include half the surface of the hand and a finger or two, or a corresponding part of the foot. Pressure on these patches, as in walking, excites a severe burning feeling. The patch can be traced out as being the parts supplied in the distribution of some one nerve or a branch of a nerve. This hyperæsthesia lasts for only a short time and is replaced by complete anæsthesia, at first superficial, but later extending into the deep parts.

Little by little, but by continuous advance and not by sudden exacerbations, the whole hand or the whole foot is involved. The parts begin to atrophy slightly and the flexor tendons to contract. At the same time lancinating pains are felt in the arm or leg. These pains are in the first stages not severe. After a period of four to six years both hands and both feet are usually affected, and distortion, due to contraction of the tendons and to the atrophy, begins to be marked. The leper is prevented now from doing work, owing to his inability to use his fingers, and in walking he has a characteristic gait, due not only to the deformity in his feet and toes, but also to the pain in his legs which is increased by motion.

At this stage, or a little later, ulcers begin to attack the parts. They commonly begin first in the feet. These ulcers have clean-cut edges, do not have a tendency to broaden out, but eat in deeply. A favorite place for a first ulcer to appear is at the base of a big toe. Its course is slow but persistent. It burrows till the joint is reached and involved, when the whole toe dies and is separated. This leaves an open ulcer which is slow to heal, but after a variable period of two months to a year it cicatrizes, leaving a characteristic rounded stump. The process of the separation of the finger is the same as that of the toes. During the continuance of one of these ulcers the leper suffers from fever, 100° to 102° F., which continues usually for weeks.

In some lepers the distortion of fingers and toes, due to the contraction of the flexor tendons, is the most marked outward sign of the disease ; in others the ulceration and loss of fingers and toes is the most prominent sign. The face has no characteristic look in this form of leprosy.

Anæsthetic patches may occur on other parts of the body as well as in the hands and feet. But in such other places no changes take place, save in some cases a scarcely perceptible atrophy.

The mode of dying is the same as in the other form of leprosy—inanition. The duration of this form is also about the same as the other form.

The mixed form is by far the most common form met with. Probably twenty cases of the mixed occur to one case of the pure tubercular or pure anæsthetic leprosy. In the mixed leprosy there is the steady, slow advance of the anæsthetic form, with its gradual distortion of fingers and toes, and its shooting pains, its burrowing ulcers, loss of parts, and low, long-continued fever, combined with the sudden eruption of tubercles, the sharp onsets of high fever, and disfiguration of features of the tubercular form.

The duration of a case of the mixed leprosy is rather shorter than that of one of the pure forms.

Case I.—Male, Hindoo, aged twenty-one ; pure tubercular leprosy ; duration of disease, six years. The first

evidence of the presence of the disease was the appearance on the chin of a little hard nodule, which was slightly painful on pressure. After some months other small tubercles appeared near the lips. He then noticed that the skin in the vicinity of the nodule had become thickened. Later on, the same characteristic tubercles appeared on the nose. When these latter appeared he remembers first to have suffered slight constitutional derangement—a fever lasting a few days. With the advent of the tubercles on the nose there was an increase in size of the tubercles on the chin. In succession the cheeks, the lobes of the ears, and the forehead were invaded. With each outbreak of new tubercles temporary ulceration of the old ones was noticed.

During the last year or two constitutional symptoms have been somewhat marked. This consists of fever occurring once in two months, 102° F. to 103° F., lasting for three to eight days, and accompanied by vomiting. Up to two years ago his feet and toes were normal in appearance. At that time they gradually began to take on a swollen or thickened look, three or four indefinite tubercles were formed on the dorsum of the foot near the toes, and the nails began to crack somewhat and grow scaly. At the present time the feet and toes have a marked puffy look, tubercles not distinctly marked. The nails are noticeably thin and scaly. His hands are quite normal; appetite good except at the times when an onset occurs. Strength at present not notably impaired.

His father was affected by this form of leprosy, and was suffering from it before the birth of this boy. The father died fifteen years after the development of his disease. The patient has one brother older and one sister younger than himself. Neither are affected; mother not affected.

Case II.—Male, East Indian, aged twenty-two; pure tubercular leprosy; duration of disease, ten years. The disease first appeared on both cheeks in the form of little hard lumps, slightly painful on pressure, and having a dark red color. After a period of about one year the lobes of the ears began to show nodules, and the entire external ear began to thicken. At the time when the ears began to show the disease the patient first had slight constitutional disturbance, the usual fever. This case has progressed slowly, an exacerbation occurring once in about a year. At those times the fever is 102° F., and disappears usually in three days. At no time have the tubercles become ulcerated. The nose began to show tubercles about two years ago. In this case the ears are the parts which show the disease most plainly. They are heavy and œdematous and nodular. The whole face is, however, taking on the characteristic lumpy and thickened look. No anæsthetic patches on the body.

His mother had mixed leprosy, and died with it after suffering from it nineteen years. His father died of old age, entirely free from leprosy. The leprosy appeared in the mother after this man was born.

Case III—Female, East Indian, aged thirty-five; pure anæsthetic leprosy; duration of disease, twenty-eight years. At the age of seven years this patient first noticed that the great toe and inner aspect of one foot were numb. She had not noticed any hyperæsthesia. After two or three years the anæsthesia was noticed to have spread over the entire foot, and the other foot was also beginning to be involved. There were pains in the legs, often severe. About five or six years after the first symptoms of the disease a sand-crack appeared in the plantar surface of the foot first affected, near the base of the great toe. At this time the patient suffered from moderate fever. After about one month an ulcer formed here, small and circumscribed. Soon after the ulcer was established the fever disappeared, the toes began to atrophy, and some contraction of the flexor tendons was noticed. The course of the ulcer was slow, but month by month it became deeper, and after about one year the toe was so affected that the patient had it removed. The resulting ulcer was considerably over a year in healing. During this time the patient suffered somewhat from fever. By this time, the seventh year of the disease, the second foot was entirely involved in the anæsthesia, and there were two other ulcers established, one on each foot. At this time patches of anæsthesia began to appear on the hands, preceded by slight hyperæsthesia. After one or two years beginning atrophy of the fingers was noticed, and the contraction of the flexor tendons in the fingers and hands began to be so great that the patient describes it as distinct sensations of drawing. Darting pains also, often severe, were complained of in the anus now, as well as in the legs.

Little by little the ulcers increased in number, eating away the toes, till now, after twenty-eight years, all the toes are gone and the feet are stumpy and somewhat atrophied. By degrees the fingers have been distorted, till now they are drawn nearly down to the palms of the hands. The little fingers are drawn down most completely. This patient has never had ulcers on her hands.

Her general health is fair, but she suffers from fever at times, and complains of pain in arms and legs, and says that she does not eat and sleep well. Menstruation regular.

An uncle and a cousin and a sister have died of leprosy, all the tubercular form.

Case IV.—Male, Hindoo, aged fifty-three; pure anæsthetic leprosy; duration of disease, nineteen years. The patient first noticed an anæsthetic patch just below the knee, and later an ulcer of the characteristic anæsthetic type appeared there. However, after more than a year it healed without attacking the bone. After two years the anæsthesia had spread to the foot and entirely involved it. An ulcer appeared under the great toe, with the result that the toe was lost in about a year. By this time the other foot had become overspread by the anæsthesia. Ulcers appeared in succession at the base of the remaining toes, and at the present time he has only three toes left, and they are in a process of separation. The patient has suffered with the usual fever and pain. One hand is entirely healthy, the other has been anæsthetic for five years. One finger of the anæsthetic hand is slightly contracted. The patient states that his health is good. The family history shows that no other members have been affected.

Case V.—Male, Hindoo, aged twenty five, mixed form; duration of disease, ten years. The first indication that this leper had of his disease was an anæsthetic patch on his thigh, and after some time a similar patch on his forearm. After about two years he noticed anæsthesia in one hand. This was preceded by hyperæsthesia. Gradually both hands were overspread by the numbness. Later both feet were involved. About four years ago he noticed one or two tubercles on his chin. One year after their appearance the lobes of his ears began to show small tubercles and to become thickened. Up to this time he had suffered only from pain in his arms and legs, but now, as the tubercles came on the characteristic fever appeared with the evolution of each new crop of tubercles, or increase in size or ulceration of the old ones. The highest recorded fever has been 102° F. There has been some vomiting.

About a year and a half ago a characteristic ulcer was formed at the base of the second toe of the foot first affected. After nine months the toe was separated. The ulcer is now partially healed. Another ulcer has formed at the base of the great toe of the same foot, and the toe is in the process of separation.

One finger of one hand is slightly contracted. In the other hand there is no contraction of the fingers. All the fingers of both hands are slightly atrophied. His father died with leprosy five years ago—the mixed form. The father developed leprosy five years after this boy was born. One younger brother is also suffering from mixed leprosy. The mother and an older sister are free from the disease.

Case VI.—Female, Hindoo, aged thirty-two; mixed

form; duration of disease, eighteen years. At the age of twelve years she noticed a patch of anæsthesia on the index and ring fingers of her right hand. This patch had also extended up on the corresponding part of the dorsum of the hand, but not on the palmar surface. After one year the whole hand had become overspread by the anæsthesia, and darting pains were felt in the arm. By the end of three years the other hand was entirely without feeling, and the anæsthesia had begun to appear in the feet. Darting pains, more or less constant, were now experienced in both arms and both legs. About this time a small nodule of about the size of a pea came on the chin.

By the end of three years more both feet, as well as both hands, were entirely anæsthetic, contraction of the flexor tendons had become somewhat marked, and nodules had appeared on her cheeks and on her ears, especially in the lobes.

With each increase of the tubercles the constitutional symptoms had been marked, even from the beginning. Fever, often severe and lasting for two weeks, was noted. Tubercles on the hands and feet and lower legs became marked at this time. At each exacerbation the old tubercles ulcerated.

When the patient was nineteen years old an anæsthetic ulcer appeared in the bottom of her right foot, near the base of the great toe. Its course was slow, but after about one year and a half the joint became affected and the toe was lost. The resulting ulcer healed slowly. As time went on the other toes were lost, one or two dropping off every year.

Nine years ago the first anæsthetic ulcer appeared on the hand. This was on the palmar surface of the second joint of the ring-finger. The joint was soon attacked and the part of the finger anterior to the ulcer was lost. The stump was enlarged owing to the modifying influence of the presence of the tubercular disease. The same thickened and swollen look of the stumps is seen in the feet.

The menstrual functions were regular till seven years ago, when the discharge became scanty and appeared at longer intervals than normal. There has been no menstrual discharge for the past three years.

Condition at the Present Time.—All the fingers and all the toes have been lost, the skin of the entire face is much thickened, the chin, the cheeks, and the forehead are studded with tubercles, from a pea to a small nut in size. The nose has a knobbed look, the ears are thickened, nodular, and have a heavy œdematous look.

As to bodily condition, the patient is not notably emaciated, but is only weak. For several months she has walked only a few steps daily. For the last year she has suffered constantly from fever, 101° F. to 105° F. Vomiting also has been persistent. She will evidently live but a few weeks longer.

This leper's father is healthy. Her mother was a leper. The mother developed leprosy one year before this child was born, and died of dropsy one year later. The patient has no brothers or sisters.

As to the contagiousness of leprosy, there is no doubt that a perfectly healthy person receiving virus into his system from a leper may develop the disease; but it is almost absolutely certain that the great majority of the human race cannot contract the disease by contact, however free. At the Leper Hospital in Madras, India, there are somewhat over two hundred and fifty lepers. Most of these are in a condition to require daily dressing of their ulcers. Three dressers are here employed for this purpose. The dressers use the naked hands in doing this work, handling and rubbing the ulcers most intimately. One dresser has been employed in this work for twelve years, another ten years, and another five years. None of them have contracted the disease. The reason may be put down that these dressers are healthy men, having no taint of leprosy in their family in past generations.

This leper hospital has been founded about fifty years. During that time a large number of persons have been employed about the grounds and in the buildings, as gardeners, ward-masters, apothecaries, etc., and there is, so far as known, only one case in which a perfectly healthy man, with a family history free from leprosy, became affected with the disease.

I have known about fifty healthy persons who have been exposed, with every seeming possible means of taking the disease into their own systems, and they have remained free from it; and I have known three persons who were without family taint of leprosy, and yet who on exposure have contracted the disease.

On the strength of these figures a rude rule might be formed that one person in every fifteen or twenty of the human race, although with no leprous taint in his family, may become a leper on association with lepers. As to the real width of the contagiousness of leprosy, this rule may be very wide of the mark, but to one who has observed leprosy carefully the opinion must be irresistible that the great majority of the human race are entirely safe though associating daily with lepers.

As to treatment, much may be done to alleviate the intensity of the disease. The frequency and severity of the attacks of the tubercular form may be in a measure abated, and the steady, relentless progress of the anæsthetic form may be somewhat stayed. The two remedies which accomplish the most decided good are gurjun-oil and chaulmoogra oil. The former was in much repute a few years back, but has in the past few years rather given place to the latter, as the chaulmoogra-oil, a newer remedy, has been found to be more active. It is the expressed oil of the gynocardæ seminis, and may be obtained in the native bazaars or from government medical stores.

Six minims of the pure oil are given in milk, morning and evening. This amount is slowly increased each day till about thirty minims are being taken twice a day. At this point the stomach usually becomes intolerant, and the remedy has to be discontinued for several days, to be begun again at six or eight minims.

A one in twelve mixture with cocoanut-oil is made up for external use. About two drachms are given to each patient daily of this mixture. This is thoroughly rubbed into the skin over the whole body, after which the leper sits for two or three hours in the sun. A bath is then taken in tepid water.

The ulcers are dressed as follows: The bandages of yesterday are taken down and the ulcers are carefully washed with warm carbolic lotion, 1 in 100. The mixture of chaulmoogra-oil and cocoanut oil is then applied to the ulcers. Or if the ulcers are especially badly conditioned, the pure chaulmoogra-oil is rubbed on with a dusting of iodoform. Small squares of cloth, spread thickly with rice paste and charcoal, are then applied to the parts till all is covered, when the whole is bandaged up. When fever comes on quinine is given. Antipyrin and its congeners will relieve fever more promptly, but less permanently.

There are three cases in the Madras Leper Hospital who have been under the Count Matei treatment. They have all become very much emaciated, which is uncommon in leprosy, and notably weakened. One of the patients, however, praises the treatment and announces his wish to resume it as soon as he is able to stand it again, as his sufferings were much less while taking it.

In the last month Koch's lymph has been given a trial with about twenty lepers. In twelve cases reaction was produced, fever of 103° to 105° F. All cases were begun on 0.001 c.c.; and in eleven cases the maximum dose of 0.01 c.c. was given for some time on alternate days. One leper, suffering from the mixed form, after two weeks' treatment was *in extremis*. Prostration was great, and for several days life was maintained only by stimulation and rectal alimentation. On the fifth day after discontinuing injections the patient began to regain strength

and after one week more was able to walk about, though strength was not fully restored.

Another leper, suffering from the tubercular form, in whom reaction was marked, developed after the sixth injection a coarse and fine papular eruption over his entire body, which is still persistent.

In all cases in which injection of the Koch lymph resulted in reaction, prostration was more or less marked; and in no case treated could any improvement be noted. The lepers themselves have become much opposed to the treatment. Although leprosy cannot be cured in the individual, it may be eradicated from the country if energetic measures are taken. In the Middle Ages leprosy was as prevalent in parts of Europe as it is throughout India to day. Leper asylums, or homes, were established here and there, and all persons suffering from the disease were compelled by force to enter them and remain there till their death. The sexes were separated. The result was that when that generation of lepers had died the disease had disappeared from the Continent.

Unless some such measures are taken in the future, leprosy will slowly spread and become one of our most common diseases.

Progress of Medical Science.

Fuchsine in Diseases of the Throat. — Dr. Bogroff claims that (1) fuchsine, like all other aniline dyes, is easily absorbed by the laryngeal and faucial mucous membrane; (2) antiseptic fluids when mixed with fuchsine penetrate into the tissues far more deeply, and act much more effectively, than when employed alone; (3) when injected into the larynx the superficial cellular elements and intercellular spaces become infiltrated with particles of the aniline dye, and thus a thin protective film is formed, which is impermeable not only by any irritating fluids, but even by gaseous bodies; (4) in cases of reactive laryngeal inflammation arising in phthisical patients from constant irrigation by the pulmonary discharge, the intralaryngeal injection of a two per cent. watery solution of boracic acid saturated with fuchsine rapidly removes the inflammatory phenomena and relieves difficulty in swallowing, etc.; (5) fuchsine proves similarly beneficial in cases of faucial mycosis. The author cites the case of a medical man suffering from that affection, in whom local irrigations with a 1 per 1,000 corrosive sublimate solution mixed with the dye quickly brought about a complete cure, after energetic antiseptic treatment by the ordinary methods had utterly failed. Dr. Bogroff believes, further, that in intra-laryngeal medication the admixture of fuchsine with other medicaments may also be found useful as a means of determining whether the drugs reach their precise destination, and whether they do so in sufficient quantities.—*The British Medical Journal.*

Billroth's Statistics on Exsection of the Stomach and Intestines.—Professor Billroth has published statistics of 124 resections which have been made in his clinic from 1880 to 1890; 83 were by himself, 3 by Wölfler, 8 by Hacker, and 15 by Saltzer and Eiselberg. The cases were all chronic processes with pyloric stenosis, malignant forms of swelling. There were 41 cases of pyloric resection (7 males and 34 females, with ages from twenty-six to fifty-eight years). The operations lasted from 1¼ to 3¼ hours, with removal of 4 to 21 ctm. of the intestine. The cause of operation was: In 28 cases, carcinoma; in 1 case, sarcoma; in 12 cases, callous cicatrices. Results: 19 cases recovered, 22 died. Of 27 typical pyloric resections, 12 were favorable and 15 fatal. Of the 13 cases of carcinoma that had endured the ordeal of the operation, 5 died after ten months, and 1 after 5¼ years, from recurrence. There were yet living three women, of whom two had been operated upon 2½ and 4½ months. There were 6 operations on account of scar stenosis, of whom 3 recovered. One patient died after three months from peritonitis, caused by an abscess in the cicatrix. There were 28 gastro enterotomies on account of carcinoma, with 14 recoveries. These all died in from one to eighteen months. Of 11 resections of the small intestine (7 males and 4 females), all were favorable. (Eight times on account of preternatural anus, once traumatic opening of intestine, and once carcinoma.) Of 24 resections of the cæcum, there were 11 on account of carcinoma (with 5 recoveries); 13 on account of fistula after perityphlitis (7 recoveries, 5 deaths, and 1 persistent fistula). Of total cases of cæcum resections, 11 deaths, 13 recoveries. Of 8 colon resections, 4 deaths and 4 recoveries. Of 7 resections of rectum all recovered, 5 times with formation of fistula.—*Wiener Medizinische Wochenschrift.*

Painful Sensations in Heart Disease.—Professor Nothnagel discusses this subject in a short paper, containing in a tabulated form the results of his investigations as recorded in his hospital case-books. He says that it is not uncommon to meet with patients complaining of painful and various unpleasant sensations in the region of the heart. If the thoracic organs are found healthy, these symptoms are usually looked upon as due to dry pleurisy, rheumatism, or intercostal neuralgia. Increased experience suggests the question, however, Why, if such is their nature, should these affections be limited to the left side, and not localized in the right half of the chest and back as well? A close relationship to the heart is indeed indicated. In some patients, markedly neurotic, subjective sensations are referred to the region of the heart, when this organ is perfectly normal. Professor Nothnagel tabulates 483 cases of valvular disease observed in six years. Here the frequency of cardiac pain differs very much with the valve affected. In disease of the aortic orifice it is much more frequent than in mitral affections, being met with most often in aortic regurgitation with stenosis of the same valve, most seldom in insufficiency of the mitral. Thus, in aortic insufficiency, painful sensations were recorded in sixty eight per cent. out of a total of 114 cases; in insufficiency and stenosis of the same valve in sixty-eight per cent. On the other hand, only 7⅔ per cent. of a total of 183 with regurgitation at the mitral valve had these sensations. It is interesting to observe that a combination of aortic and mitral leakage produced the symptoms in only eighteen per cent. This result confirms those of other authors who have generally limited themselves to recording the so-called steno cardial (anginose) attacks with pain usually radiating down the left arm. These statistics include, besides, less definite painful disturbances. Most authors mention the steno-cardial attack only in aortic disease, and Germain Sée states they are limited to this form of valve affection. This Nothnagel confirms generally; but he gives a case, on account of the rarity of such attacks, where the lesion was a pronounced stenosis of the mitral orifice. Other forms of painful sensation complained of are sticking, tearing, burning, boring pain in the præcordia, which is almost continuous. Sometimes the feeling is as if the heart would be plucked out. Or paroxysms of violent pain, together with sudden and severe palpitation, may occur. In both cases the pain may radiate into the left side or back. Still further, there may be a feeling of a foreign body in the left chest. It is noteworthy that objective alterations of sensation may frequently be present on the skin, and not only with steno-cardial attacks, but likewise in the other forms. The skin over the præcordia may be more sensitive than that of the right side, or there may be a feeling of pins and needles, and this may extend to the left side of the thorax and back, close to the vertebral column. Firm pressure against the intercostal spaces in the cardiac region produces tenderness there, or even actual pain, and this tenderness may often be observed in the whole region of the third to the seventh intercostal nerves.—*Montreal Medical Journal.*

Clinical Department.

A CASE OF RETRACTION OF THE EYEBALL.[1]

By FREDERICK E. CHENEY, M.D.,

ASSISTANT SURGEON TO THE MASSACHUSETTS CHARITABLE EYE AND EAR INFIRMARY; OPHTHALMIC ASSISTANT TO THE OUT-PATIENT DEPARTMENT OF THE MASSACHUSETTS GENERAL HOSPITAL.

THE patient whose case I have to report is a young woman of English parentage and birth, aged twenty-seven. She was first seen by me at the Massachusetts Charitable Eye and Ear Infirmary, March 19, 1891, when she gave the following history: There has always been more or less discomfort and pain in the head after reading or other near work; for the last three months the headaches have been severe and almost constant. While living in London, two or three years ago, she consulted Mr. Nettleship, and was examined by a number of other gentlemen at that time. The eyes have never moved freely from side to side, and the right has always appeared somewhat smaller than the left. Double vision is noticed occasionally after prolonged use of the eyes, but disappears quickly when the work is discontinued. Her general health is good, and no troubles other than those mentioned are complained of.

Upon examination the right eye appears somewhat smaller than the left, due probably to its being a little deeper seated in the orbit. The lateral movements are decidedly defective; movement outward is absent in the right eye and very limited in the left; movement inward is very limited in the right eye, but fairly good in the left, though less than normal. No limitation in the vertical movements could be detected. When an attempt is made to converge strongly, or to follow an object far to the left, the right globe sinks back into the orbit to a very noticeable degree. As the eye recedes the upper lid droops, and, retaining its contact with the surface of the eyeball gives a sunken appearance, suggesting the presence of an atrophied globe behind it. The lower lid, however, does not sink backward, but is separated from the globe over its entire surface by a very considerable space. After the first effort the eye comes forward a little, but does not regain its normal position until the effort is discontinued. The degree of retraction was measured on three different occasions and found to vary from three and one-half to four and one-half millimetres. There is also a slight retraction of the left eye, but it is not sufficiently noticeable to attract attention unless examined with some care. The pupils are equal, of normal size and reaction; the accommodative power is good; the transparent media and fundus of both eyes are perfectly normal. The vision of the right eye with $-.25$ D. $-.75$ D. cyl. axis $100^\circ = 1$, and that of the left with $-.75$ D. $-.50$ D. cyl. axis $30^\circ = 1$. By the vertical diplopia test a prism of three degrees, base out, is required to place the images in the same vertical plane; the adducting power is eighteen degrees, the abducting power two and one-half degrees; a prism of two degrees can be overcome with its base up or down before either eye. Glasses correcting the refractive error, combined with a one and one half degree prism, base out, before either eye, were prescribed, and have relieved in a great measure the asthenopic symptoms complained of.

The point of special interest in this case, which is evidently one of congenital ophthalmoplegia externa, is, of course, the unusual retraction of the right eye when an attempt is made to rotate the eyes strongly inward. As to the cause of this retraction, it is probably brought about by the combined and simultaneous action of the superior and inferior recti muscles in attempting to supplement the defective internus. As is well known, these two muscles acting together tend to rotate the eye inward and also to draw it backward into the orbit; and although under normal conditions the internal rectus requires little or no assistance in converging, it is easy to understand, with the existing conditions in this case, that the added converging power will be of much value in enabling the patient to maintain binocular vision for near work. If the left internus were as defective as the right, the assistance given by these muscles would probably not be sufficient to accomplish the amount of convergence necessary, and the patient would soon learn to suppress one image; but with the vision about equal in the two eyes, and binocular vision for distance being maintained with but little effort, it is only natural that binocular vision should be attempted for the near and obtained in the manner suggested. At the reading distance the muscular power required in converging is not great enough to produce any very noticeable sinking of the globe, but an attempt to fix objects at twenty centimetres results in a marked retraction, and the degree increases as the distance of the object is decreased.

The amount of resistance offered by the post-ocular tissues in this case, when pressure backward is made on the surface of the eye, is of interest in connection with the degree of retraction, and, as would naturally be expected, is found to be considerably less than normal. This may, of course, be accounted for by supposing a congenital want of development of the fatty and connective tissues; but another idea suggests itself, namely, that the frequent and long-continued pressure made by the globe has resulted in their partial atrophy and absorption. If the latter supposition is correct, a still greater degree of retraction may be found after a number of years than exists at the present time.

[1] Case shown at the meeting of the New England Ophthalmological Society, April 2, 1891.

A CASE OF RETAINED PLACENTA TWENTY-TWO DAYS AFTER A MISCARRIAGE OF A FOUR-MONTHS' FŒTUS.

By J. J. LAMADRID, M.D.,

BROOKLYN, N. Y.

THE following case is reported in the belief that it is rare and interesting, the writer having never read of or seen one like it in an experience of twenty years' active practice:

Mrs. A. H——, aged twenty-eight, healthy, and the mother of two living children, considered herself pregnant in the fourth month. On the afternoon of September 3, 1891, she felt a sudden rush of water coming from the vagina, but as she had no pains and did not notice any blood passing from her, she did not feel alarmed about it, nor thought it necessary to have the advice of a physician. Four days later, however, I was sent for in haste, about one o'clock in the morning, the woman's husband stating that he thought his wife was going to have a miscarriage. When I arrived at the house I found, on examination, a four-months' fœtus lying close to the vulva, the mother stating that she had felt something come away, but that she had had no pains and no discharge of any kind. Wishing to verify this fact myself I now inquired particularly if she had suffered any pains at all, or had lost any blood. In answer to this inquiry she said: "Why, doctor, I do not know what to think of this myself, for I can assure you I have not experienced any pains, except a heavy feeling around my back, such as I feel whenever I am about to be unwell, nor have I lost or passed any blood." I then proceeded to investigate the condition of the womb by placing my left hand over the hypogastric region and introducing my right index-finger into the vagina for the purpose of removing the placenta and any clots of blood I might find within. I found the os uteri high up and almost closed, that is, I could hardly get my index-finger into its cavity beyond the first joint. Under the circumstances, I prescribed small doses of ergotole (gtt. v.) every hour at first until six doses were taken, after that every two hours, also quinine, in hopes of exciting uterine contractions which

would expel the placenta. The following day another examination with the finger was made, but there seemed to be no perceptible change; there were no pains and no discharges of any kind. I advised her to continue the same treatment, and the use of vaginal injections of carbolized warm water. The patient was kept under close observation for a week, during which period she was examined from time to time, to see if there was any smell or lochial discharges, but none was detected. After the tenth day the patient was allowed to get up and walk around. At the same time my visits were discontinued, and I left instructions that I should be sent for if she felt any pains or noticed any dirty discharge. Since then the patient has been able to go out and attend to her home duties. On the morning of September 29th I received a telephone message urging me to come to the house at once. When I arrived there I found the patient was all dressed and walking around. She now showed me a vessel containing some dark, clotted blood and the entire placenta, free from any unpleasant odor. On a closer examination I found this in an advanced state of fatty degeneration. She had no pains, but a peculiar sensation that something wanted to come away, which it did as soon as she sat on a vessel. Another peculiarity of this case is the appearance of the milk three days after the placenta came away, instead of, and at the time the fœtus came away. Since then the patient has continued doing well, and is now enjoying good health.

I have no comments to make on this remarkable case, except to suggest the following hypothesis: Did the fatty degenerated condition of the placenta have anything to do with the absence of pain and loss of blood?

412 Greene Avenue.

A REMARKABLE CASE OF GUNSHOT WOUND IN EACH EAR, WITH RECOVERY.

By L. TIBBETS, M.D.,

Rockford, Ill.

The history of this case is one of attempted suicide, and is of special interest, as showing the tolerance of the parts, and the failure of an attempt at self-destruction by shooting directly in each ear with a 41-calibre Derringer pistol.

I was summoned on July 10, 1890, at 4.30 P.M., to see A. W. W——, aged about forty; weight, one hundred and ninety pounds; height, six feet, who had shot himself at the Police Headquarters with suicidal intent. I arrived within eight minutes from the time of shooting, and found the patient, as he fell, lying on his face, apparently dead, with blood flowing from his ears. The finger could be introduced into each ear for about two inches. On rolling the patient over, blood was seen to be flowing also from his nose and mouth. His eyes were rolled up and open, the respiration was feeble, and the heart's action rapid and weak. On introducing my finger in the ears I could distinctly feel the rough edges of bone in the track of the ball. The left auditory canal was badly lacerated, and a portion of the tissues surrounding the meatus was protruding, resembling the point of exit of a ball. He vomited blood freely, and after half an hour resisted, unconsciously, any efforts to relieve him, throwing himself around violently and moaning, indicative of severe pain. I administered an hypodermic injection of morphine ¼ grain, which quieted him for one hour, and when the same symptoms reappeared the morphine was repeated. I syringed out the ears with a two per cent. solution of carbolic acid. He rested quietly until 8 P.M., when he was placed in the patrol wagon and taken to his home. After arriving the hypodermic was repeated, as he appeared to be suffering considerable pain. Cold cloths, wrung out of two per cent. solution of carbolic acid, were also applied, and changed frequently during the night. At about midnight he muttered a few words, but was apparently unconscious of what he said. When he tried to drink water he could not, the water returning through the nose. He could open his mouth only half an inch. The following morning Dr. D. S. Clark, of this city, called with me. We probed the wounds with a Nélaton probe, but did not detect any evidence of the balls. The probe was inserted about two inches in each ear. Iodoform was dusted in the ears, and the cold applications to the surfaces were continued for two weeks. There was very little swelling or inflammation; the temperature registered 99° F. most of the time. He continued raising blood by hawking, and complained of severe pains over the right side of the thorax, below the right nipple, and also on the right side of larynx. About the seventh day copious sanguino-purulent discharge came from the posterior nares and vault of the pharynx, which was cleansed with a twenty-five per cent. solution of peroxide of hydrogen. All efforts at swallowing resulted as from the first. Only fluids could be taken, and they would run out of the nose, only a portion being swallowed. The man also complained of severe pains in the posterior nares, and had difficulty in speech as he could not use the lower jaw. These conditions led me to think that the ball had deflected downward and lodged near this part. I made a number of examinations in the wounds of entrance for the balls, but without any success until the 26th, when I found unmistakable evidence of their location in each ear, about two inches from the meatus, in the course of the auditory canal, upward and forward. I introduced an ear speculum, and with the aid of head-mirror and a reflected light could see distinctly each bullet; the roughened edges of bone were leaded from the balls in their transit. I improvised an iron drill, one-eighth inch in diameter, with a ring on the other end, to bore into one of the balls to attempt its extraction. I succeeded in boring a hole longitudinally, and then, with an iron screw, secured it firmly in the ball; but with the force employed the threads of the screw cut out the lead and pulled out. I then used a larger one, with the same results. After drilling the hole the patient said he could hear better, as he had been quite deaf. I poured in a few drops of twenty-five per cent. solution of peroxide of hydrogen, which passed through the Eustachian tube into his mouth, as evidenced by the frothy expectoration. His hearing was very materially improved, and he said he heard the crackling of the peroxide; the pressure, or "stuffy feeling," as he described it, was relieved. All efforts to remove the balls proved useless, and as they were impacted in the bones, and partially flattened, I concluded any further efforts would do more damage than allowing them to remain. The wounds were healing in a healthy manner, and the auditory canal drained the parts. The right eye could not be closed fully, and even when he was asleep it remained partially open. The muscles of right side of the face were also paralyzed. Consciousness partly returned on the second day, but the man could not talk coherently. The first evidence of rationality was on the third day, when he would repeat, "Is this all a dream?" After he was able to walk around, which was three weeks from the date of the shooting, his gait was normal. Sleep was normal most of the time, and he did not complain of dizziness. The discharge from the ears had nearly ceased by September 15th. He gave me his history of the shooting. He said he took two 41-calibre Derringer pistols, put one in his left hip-pocket, the other he carried in his right hand, and went up to the police court-room. As he entered the door he placed the muzzle of the pistol in his right ear and fired; he remembered that he went down on his knees, and then, to make sure, he reached around to his left hip-pocket, took the other pistol, put it in his left ear and fired. Then all was a blank for a while, how long he could not tell. He disappeared about September 15th; but I heard from him, indirectly, over one year later, to the effect that he was engaged in driving a hack, and did not suffer from any disability, except the inconvenience of partial loss of hearing.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, November 7, 1891.

THE CUBAN MEDICAL CONGRESS.

THE Second Medical Congress of the island of Cuba will be held in Havana in January, 1892, under the presidency of Dr. Juan Santos Fernández. The proposal to hold a congress of Cuban physicians was made by Dr. Enrique Lopez at a meeting of the Society for Clinical Studies in Havana, on September 6, 1888. The idea met with a favorable reception, committees were formed, plans were discussed, rules drawn up, and a date set for the first congress. This was opened on January 15, 1890, in the hall of the Royal Academy of Sciences of Havana, by Dr. Tamayo, President of the Society for Clinical Studies. The attendance was large, a rather formidable number of papers was presented, but they were of no mean order of merit, the enthusiasm was great, and the congress was unanimously pronounced a success.

We congratulate our colleagues in Cuba on the formation of this association and we wish it every success, and we do so actuated not only by a feeling of good-will, but by the direct personal interest that everyone in this country has in the results of its deliberations. Science, indeed, has much to gain therefrom in the better knowledge concerning tropical diseases, which will doubtless spring from the discussions taking place before this association; and as physicians we shall look forward with much interest to the publication of the volume of "Transactions" of this Second Congress. But apart from this, the members of the Cuban society have a duty to perform, in the fulfilment of which they will confer a direct benefit upon every inhabitant of the Eastern and Southern United States.

Nearly every summer the people in these regions are threatened with yellow fever, and occasionally suffer from more or less wide-spread epidemics of the dread disease. The germs may now and then be brought in ships coming from the Spanish Main, from islands of the West Indies, or even from Brazil; but in a large proportion of cases Havana is the starting-point of our epidemics. There the disease is endemic, and hence it spreads to other points whenever the conditions become favorable. It is the nearest tropical port of consequence to our shores, and communication between it and our own ports is constant. Four lines of steamers, at least, make regular and frequent trips between Cuba and the United States, to say nothing of the numerous sailing vessels and occasional tramps passing between the two countries.

During the First Cuban Medical Congress there were six papers on yellow fever presented out of a total of about eighty. So we see the subject is one that interests the physicians of Havana; and the formation of such a congress as this will doubtless stimulate them to further study of the disease in all its aspects, of the means best suited for its prevention and extinction, as well as its treatment. And then we, as well as they, shall reap the benefit.

ANOTHER CIGARETTE FIEND.

THE small boy, the broker's clerk, and the young doctor are no longer to enjoy a monopoly of cigarette-smoking, if a recent press despatch concerning a discovery of Dr. Ohmann-Dumesnil, of St. Louis, be correct. It seems that he was led to investigate the cause of holes occasionally seen in cigarettes, and found that they were caused by an insect. According to the account given, this little bug, one of the numerous family of coleoptera, watches his opportunity when the cigarette box has been carelessly left open, flies in, bores a hole in the paper wrapper of the cigarette, lays an egg carefully in the tobacco, and then departs when the lid of the box is again raised. If the cigarette is not consumed very soon, this egg develops into a worm which feeds upon the tobacco surrounding it, and thrives thereon—unlike the small boy.

The report continues:

"What do you think of a cigarette that has entertained one of these bugs, doctor?"

"I consider such a cigarette a poison, and I attribute many mysterious cases of bronchial affection to this source."

This may be sad news to the cigarette smoker, or it may be that he will not care whether bugs are there or not. So let the worm have its perfect work.

THE TIN-PLATE IN SURGERY.

THE intense but somewhat artificial excitement over the tin plate industry which political journals have worked up, has, we presume, not much affected the medical mind. We do not care to have it do so; and yet, according to Dr. Elizabeth Reifsnyder, of Shanghai, China, the tin-plate meets a long-felt need in medicine, and is destined to be the treatment of the future for ulcers of the leg. As there are over three hundred millions of people in China, and as China, we are told, abounds in leg ulcers, the future of the tin-plate industry presents a very stimulating picture to the imagination.

The good news about tin-plate did not start from Shanghai, however, but from the equally interesting town of Philadelphia. Dr. E. R. Moras showed its value nearly a year ago, while Dr. Reifsnyder has been trying it on the Chinese for four months.

There are six treatments for ulcers of the leg, according to Dr. Moras: The moist treatment with ointments, washes, etc.; the dry treatment with powders; rest and compression with bandages; skin-grafting; transplantation of a flap; the tin-plate.

The technique of this last measure is as follows: The surgeon must have bichloride of mercury solution, 1 to 1,000, oiled silk or rubber tissue protective, common sheet-tin, adhesive plaster, dressing material, and bandages.

The ulcer and surrounding tissues are cleansed with bichloride solution, then the ulcer is covered with a piece of protective that has been soaked in the same solution. Not only is the ulcer covered, but the protective is cut one-third of an inch larger than the ulcer. The tin is a trifle smaller than the protective, so that it does not touch the skin. Tin also has been soaked in the bichloride solution for a few minutes. With one or two strips of adhesive plaster the plate is firmly fastened, a few layers of gauze over the plate and surrounding tissues, and all held in place by a roller bandage. The plate must be adjusted with uniform pressure.

Impress upon the patient's mind that the plate is not to be removed. The outer dressings have been removed and paper has been substituted for gauze, and the healing process still gone on. Dr. Reifsnyder adds that after giving the tin-plate treatment a trial of over four months, "we have found that the ordinary chronic leg-ulcer heals in from six weeks to two months. The patients suffer no inconvenience or discomfort while wearing the plate, and in most cases are far more comfortable than they were before its application."

THE NEW FREE BATHS.

The inauguration of this most practical charity, reference to which was made in our news columns some weeks ago, may be regarded as the occasion for much congratulation on the part of those who have made a study of the social conditions in this great city. One obstacle in helping the poorer classes is the false pride which the latter have, and which makes them rather resent the acceptance of any charity unless the latter is veiled under some other name. Already a complaint has been published in one of the daily papers by a resident of the down-town district where the baths are in operation. He tells the managers of the society that they have the words "Society for Improving the Condition of the Poor" entirely too prominently displayed in their new building. They have put their own price on the baths. If a person pays it, why should he be considered as poor?

This is, of course, very silly reasoning, but it represents an element of character among the classes for whom efforts are being made which must be taken into account by all charitably disposed persons. It is confined, happily, to the minority. The greater mass of the people for whom the baths are designed have evidenced their appreciation by a most liberal patronage. It is not unlikely that this will greatly increase, now that the cooler weather has come and the city baths have been closed. During the first two weeks of the existence of the baths at the Demilt Dispensary, over one hundred and fifty availed themselves of the privilege of the three days devoted to men. On the days devoted to women the attendance has been almost nil, though of course a woman has been in attendance at those times. There seems to be no reason why women should not patronize the house-baths as frequently as they do the city-baths during the summer.

The baths at the Demilt Dispensary are at present six or eight in number, and if experience warrants, the whole basement of the building will be given up to that purpose. The patron can have a shower or tub bath, as he may prefer, with either hot or cold water. The rooms are divided into two parts by a partial partition. In the outer space the clothing can be left, while the bath is taken in the inner. The fittings are of polished marble, and it goes without saying that the plumbing is first-class.

Anything which leads a man to take two baths where he only took one before, may confidently be regarded as a great benefit to him. The new departure has had no opposition, but only lethargy, to contend with, and as soon as its benefits become more widely known we may hope for ample and satisfactory results.

LATIN IN PRESCRIPTIONS.

There occur periodically attempts to induce medical men to write prescriptions in the vernacular. Several legislatures have even been appealed to, and laws have been framed for the abolition of Latin. The arguments for this are generally that the latinity of modern prescriptions is very bad, that the practice is simply the survival of an ancient and useless custom, and that it is pedantic and useless, and conceals from the patient things that he ought to know. We regard it as fortunate that the good sense of the profession has not been imposed upon by these specious arguments. The reasons for using Latin in prescriptions are sound and practical. The chief one is, that it is of the greatest importance to have drugs given names which will not be changed with fashion or locality, and which will be understood all over the world. In a recent article upon this subject Professor Joseph P. Remington (*Journal of the American Medical Association*, October 21, 1891) has given a long list of plants whose English names indicate three or four different substances. Thus to illustrate:

Lungwort may be either Pulmonaria officinalis or Variolaria faginica.

Masterwort may be either Angelica atropurpureus or Imperetoria ostruthium.

Matico may be either Piper angustifolium or Artanthe elongata.

Milkweed may be either Asclepias tuberosa, Apocynum androsæmifolium, or Euphorbia corollata.

Monkshood may be either Aconitum napellus or Leontodon taraxacum.

Partridge berry may be either Gaultheria procumbens or Momordica balsamina.

Pellitory may be either Anacyclus pyrethrum or Xanthoxylum fraxineum.

Prickly ash may be either Xanthoxylum fraxineum or Aralia spinosa.

Rattle root may be either Macrotys racemosa, or Cimicifuga racemosa, or Cicuta virosa.

Rattlesnake root may be either Goodyara pubescens, Nabulus alba, Cimicifuga racemosa, or Polygala senega.

Snake root may be either Cimicifuga racemosa, Aristolochia serpentaria, Eryngium aquaticum, Liatris spicata, Asarum canadensis, Polygala senega, or Eupatorium aromaticum.

Spice berry may be either Gaultheria procumbens or Laurus benzoin.

But besides this, it would add immensely to the difficulties of practical therapeutics, if in the literature of foreign languages the vernacular was used to designate

the drugs employed. Such difficulty is indeed experienced to some extent already with the French, whose prescriptions are often unintelligible to any but Frenchmen.

There is no doubt a need of reform in the latinity of modern prescription-writing, but the abolition of the use of this language would be a misfortune.

MEDICAL JOURNALS IN THE WEST.

We have a great respect for the journalistic skill and enlightened literary intelligence of our Western colleagues; but it appears as if the medical journal industry among them was being slightly overdone. There is no ethical objection to every doctor publishing his own medical monthly; and that seems to be the tendency over a large and cereally rich area of which St. Louis is perhaps the centre. But while there is nothing unethical in the multiplication of medical monthlies, it sometimes appears as if there was a malicial disadvantage to the profession in general. For it is confusing, expensive, and time-consuming to go over them all and extract the rich kernels from the sometimes rather thickly-investing shell. Besides, one cannot but think of the brilliant journalistic effect that would result if the rich material, now so widely distributed, were combined in one solid and successful periodical. The medical journalism of the Great Lakes and the Mississippi Valley contains the promise and potency of great things, but the realization will be deferred as long as with every moon a new journal comes. Not but that we believe in local journals; they are indispensable in promoting medical co-operation, stimulating literary activity, and diffusing practical knowledge. But there may be journalistic superfetation, and we fear that the South and West are becoming affected therewith.

THE THERAPEUTIC VALUE OF A GOOD SHAKING.

An esteemed colleague on the other side of the water had been suffering for several weeks from a most obstinate attack of catarrhal jaundice, which resisted every form of medication that he or his friends could think of or found recommended in the text-books and therapeutic manuals. In the midst of his distress, and when he had about abandoned all hope of ever again eating a square meal with relish, or having a normally colored alvine evacuation, he found himself obliged to undertake a journey of some length by rail. He did not want to go, but duty called him, so he obeyed. Soon after arriving at his destination in the evening he had an attack of colic, which was succeeded by a sensation as if a syringeful of warm water had been discharged from the region of the gall-bladder into the stomach. The sensation was a novel one, and while pondering upon its significance he fell into a deep and dreamless slumber, from which he did not awaken until the following morning. Upon rising he found, to his joy, that he was hungry, and ate a good breakfast with better appetite than he had had for over five weeks. The meal was followed by a very satisfactory stool, in which was seen a considerable quantity of bile. From that time his recovery was rapid. The cure was attributed to the dislodgement of a plug of mucus from the bile-duct in consequence of the shaking-up on the railroad, for it must be remembered that among the effete nations of Europe vestibule trains are not, and the rails are often laid in such a fashion as to cause the greatest possible jolting. But this discomfort was a blessing in disguise to our suffering *confrère*, and so pleased was he with the results that he urges all who may be afflicted as he was to take a railroad ride, or if unable to do that, to drive in a springless wagon over a corduroy road. To those who may be so situated that they can do neither he recommends a self-inflicted shaking by jumping up as high as possible and coming down on the heels. He has succeeded in curing two cases by this simple measure, and regards it as far more efficacious than the most complicated drug treatment. The school-boy has long experienced the application of shaking as a remedy in the moral order, and now he will learn that it also relieves him of bile—pure, material, bitter bile. Thus the world moves, and the god of healing smiles approvingly upon the upward strivings of his devotees.

A NATIONAL PENSION FUND FOR NURSES.

At a meeting held in this city last week, an organization for securing pensions for nurses was successfully established. Through the liberality of Mr. J. Pierrepont Morgan and Mr. D. O. Mills, the sum of $100,000 was subscribed. The objects of the work are briefly these:

1. By the payment of a stipulated sum per month the nurse becomes entitled to a specified annuity, to begin at a stipulated age.

2. In case of sickness she is further entitled to a certain weekly amount as "sick pay."

3. In case of absolute necessity, compelling her to discontinue her monthly payments, she does not lose what she has paid, but may withdraw it with interest at a certain moderate rate. This interest is added yearly to the total amount of her payments, and so she receives compound interest on her whole savings, whenever withdrawn.

4. In case of her death, the amount of her savings, with compound interest at the stipulated rate, is paid to any person whom she may have designated to receive it.

Thus, we are told, the pension fund answers, within certain limits, the purpose of an annuity insurance, a sick-pay insurance, a savings bank, and a life insurance; all at the most moderate rate, since the expenses of the business are provided for; and with ample security of permanence and solidity, since there is capital behind it, and the investments are made by gentlemen of eminent financial ability whose services are given gratuitously to the work of the fund.

The pension fund is evidently a highly desirable kind of a Benefit Society to which philanthropists as well as the nurses contribute. We congratulate the nurses on the fact that energetic and benevolent gentlemen are willing to do so much for them, apparently unasked. For, curiously enough, the nurses themselves do not seem to figure at all in the proceedings for organization. Doubtless this seemed hardly necessary.

We are curious to know if there will soon be started a pension fund for some other deserving class of workers. Medical men would, we have no doubt, labor more cheerfully and happily if they knew that there was a fund on which they could draw in their old age.

News of the Week.

Health-resorts Along the Riviera. — Dr. Edmund Charles Wendt, of this city, who sailed on Thursday on the Fürst Bismarck, is commissioned by the MEDICAL RECORD to devote the coming winter season to an exhaustive study of the climatic and sanitary conditions of the health-resorts along the Riviera. Dr. Wendt will also visit Florence for the purpose of ascertaining the causes that led to the recent outbreak of typhoid fever in that city. He will likewise report on the sanitary condition of the other Italian cities frequented by American tourists. The preliminary organization of the International Medical Congress, to convene at Rome, will also receive his attention.

Reception to Professor N. Senn, of Chicago.—Dr. B. A. Watson gave a reception at his residence, in Jersey city, to Nicholas Senn, M.D., Ph.D., Professor of Surgery, Rush Medical College, Chicago, on Thursday evening, October 29, 1891. A large number of representative medical gentlemen from Jersey City and elsewhere were present.

A New Use for Tuberculin.—The Board of Health in Philadelphia has, according to the New York *Times*, begun an inquiry concerning the sale of the milk of consumptive cows in that city. It appears that this action was suggested by the report of the investigation made by a committee which was instructed, by the Veterinary Department of the University of Pennsylvania, to test the value of Koch's tuberculin by experiments in which cows should be the subjects. The committee began its work last spring, and its conclusions are that, while the tuberculin has no value as a curative agent, it is very useful as an agent for revealing the presence of tuberculous disease. It is difficult to detect tuberculosis in cows in the early stages of the malady, and as it is of great importance that the actual condition of diseased milch-cows should be known, the tuberculin may possibly be of great service to the human race, even if the condition of consumptives cannot be improved by the direct application of it. The committee was led by the result of its experiments to publish a most emphatic warning against the sale of the milk and flesh of tuberculous animals, and this has directed the attention of the Board of Health to the milk-supply.

Chlorine Water and Quinine in Typhoid Fever.—Dr. Burney Yeo recommends as the best antiseptic in typhoid chlorine water with quinine. It is made by putting thirty grains of powdered chlorate of potash into a twelve-ounce bottle, with forty minims of strong hydrochloric acid, the bottle is to be corked, the gas allowed to generate, then water is to be poured in little by little and well shaken with the gas, and finally twenty-four or thirty six grains of quinine and an ounce of syrup of orange-peel are to be added; of this mixture an ounce is to be given every two, three, or four hours. In the early stage, first week, one or two full doses of calomel, five to ten grains, are recommended, especially if there is constipation.

Bromol, which was introduced into therapeutics by Dr. Rademaker, is a chemical compound, tribromophenol and is obtained as a white flocculent and gradually crystallizing sediment when bromine water is added to an aqueous solution of carbolic acid. Pure tribromophenol occurs as a white crystalline substance which melts at a temperature of 203° F., and is nearly insoluble in water, but readily so in alcohol, ether, chloroform, glycerine, and in fatty and ethereal oils; the odor is disagreeable, like that of bromine, the taste is sweet and astringent. According to some experiments previously published by Grimm, the antiseptic virtues of bromol would seem to rival those of carbolic acid. When it is applied to recent wounds it causes a sensation of burning and has a caustic action; it stimulates atonic granulations, and produces a favorable effect on tuberculous processes. In gangrene it acts as a powerful disinfectant, and accelerates the separation of dead matter. Dr. Grimm applied it to wounds either in a pure state or mixed with some indifferent powder, and as an ointment. He also employed it to impregnate bandages. He considered it inapplicable to the mucous membrane of the mouth, nose, and pharynx on account of its caustic properties. Dr. Rademaker uses bromol either in substance or in solution of olive-oil of the strength of 1 in 30, or as an ointment of the strength of 1 in 10. In diphtheria he brushes the membrane with a glycerine solution of the strength of 1 in 25. As tribromophenol remains undissolved by the gastric juice and is only slowly acted upon during its passage through the intestinal canal, Dr. Grimm made use of it as a disinfectant of the bowel, giving in doses of from three to seven and a half grains per diem. Dr. Rademaker also has administered it in cholera infantum in doses of from five to fifteen milligrammes, and has prescribed it in typhoid fever. It is secreted by the kidneys in the form of tribromophenol-sulphonic acid.—*The Lancet*.

The Tri-State Medical Association of Tennessee, Arkansas, and Mississippi will convene in the city of Memphis on November 19th and 20th.

The Arkansas and Missouri Association of Railway Surgeons held its second session at Newport, Ark., on the 27th ult.

A Bogus Diploma Mill is said to exist in Montreal, Canada. The diplomas purport to be issued from the University of Victoria.

The Vis Medicatrix is a new bi-monthly journal of medicine, and is the organ of the Iowa State Medical Society. It is edited by Dr. Woods Hutchinson, of Des Moines.

Laparotomy for Intestinal Perforation in Typhoid Fever has been performed twelve times, with but one success. Dr. Da Costa, in a discussion on this subject, said, as a result of his experience in two cases, he would never sanction the operation unless a causal appendicitis could be made out, or unless for the relief of peritonitis.

A Pasteur Institute in Cochin China.—A Pasteur Institute was opened at Saigon, on June 1, under the auspices of the French Government. Though primarily intended for the practice of anti-rabic inoculation, the work of the institute will extend over the whole field of micro biology.

A Suit for $20.000 was recently brought against a prominent physician of this city, by Dr. Gould, for al-

leged slanderous statements. These statements prevented him, he asserted, from becoming a member of the New York Academy of Medicine. A verdict was promptly given in favor of the defendant. Such suits show, perhaps, the high pecuniary value attached to membership in the Academy, but they are disquieting to the Committee on Admissions.

The Influenza is said to have reappeared in Vienna, Bucharest, and Berlin, and also to be prevailing in Russia.

Woman's Medical College of St. Louis.—This institution was first named the Rachel College of Obstetrics and Nursing, and its scope of operations was fairly outlined by that name; but since getting the movement well under way it has been decided to make a woman's medical college out of it.

The Cost of Births, Marriages, and Deaths.—Someone estimates that getting born costs the people of the United States $250,000,000 annually; getting married, $300,000,000, and getting buried, $75,000,000. To the economical mind these figures will at once suggest the most advantageous course of conduct.

Medicine at the World's Fair.—We are informed that the Medical Director of the World's Fair is Dr. John E. Owen, and that he has promised that women shall receive official recognition upon the medical staff. The number to be appointed has not yet been announced, but assurance has been given that women physicians will rank with men and share the duties of the exhibition hospital. The profession will look forward with interest to Dr. Owen's Exhibition Hospital, with its exhibition staff of male and female doctors. According to the reports of the last Exposition at Paris they may expect about 732 cases of hysterics, 197 syncopes, 11 deaths, and 3 births. This will be enough to make the hospital interesting as an exhibition.

A So-Called Double-Headed Boy has been on exhibition in this city and has been examined by medical men. The boy is a fine, bright, well-developed youth of eighteen years, and attached to the extremity of his sternum is the incomplete figure of a twin. The arms are given out, without scapulæ, from the sternum of the young man. The trunk is short and incomplete, but it terminates in a pelvis with which the legs are connected. There would seem to be no separate heart in the parasite, and the pulse, both radial and axillary, is synchronous with that of the autosite. There is anchylosis of the joints in the undeveloped child. The young man is conscious of a sensation when this second body is roughly touched. It is said to be the opinion of competent surgeons who have examined the boy that the parasitic growth could be removed without serious injury to him.

Artificial Cornea.—The *Berlin. Klin. Wochenschrift* publishes a seventh case of transplantation of cornea by Professor V. Hippel, of Konigsberg. There was a dark-brown central decoloration of the cornea, three millimetres in diameter, and reaching down to the membrane of Descemet, which had been caused by the action of nitrate of silver. Cocaine having been applied, the non-transparent part of the cornea down to the membrane of Descemet was cut into by a little trephine, the crown of which was four millimetres in diameter, and carefully removed. The author then excised by the same means a similar piece from the whole thickness of the cornea in a young rabbit, and transplanted this to the eye of his patient. It filled the wound exactly and was on a level with the rest of the cornea. Iodoform was applied, and both eyes were bandaged. Healing proceeded without any trouble, and in six weeks the patient was discharged with a completely transparent cornea.

The Virchow Medal.—It is said that the medal presented to Professor Virchow, at his recent jubilee, measures 118 millimetres in diameter, and is made from eighteen-carat gold. The front of the medal bears a bust representation of Virchow in relief. The back is adorned with an heraldic design, the allegorical figures of medicine and pathology, microscopes, books, skulls, and an Egyptian mummy.

"**No Slanders of the Medical Profession** are allowed in Vienna," says the London correspondent of *The Lancet*, who adds: "It has been reserved for the dramatic censor of Vienna to show thus publicly the esteem in which he holds medicine and its votaries by declining, for the reasons above mentioned, to allow Mr. Abraham Dreyfus's comedy, entitled 'From 1 to 3 P.M.' (the hours of consultation of most medical practitioners on the Continent), to occupy the stage of the Carl Theatre. The *Temps*, from whose columns I cull the information, alleges that the piece, the *première* of which was announced for the 9th inst., was interdicted because it 'portait atteinte à la considération du corps médical.' The event is sufficiently rare to merit recording in a representative medical journal."

The Frogs and the Surgeons.—It is stated that the surgeons of the New York Hospital some little time since made an unsuccessful attempt at skin-grafting with the skin of frogs in a case of extensive burn. Six dozen of the finest specimens to be had in the market were selected and fed and attended with the greatest care, so as to have them in the best possible condition at the time of the operation. Some thirty grafts about the size of a twenty-five cent piece, taken from the backs of as many well-fattened frogs, were used at one time, and it seemed at first that there was every prospect of success. The final result, however, was a total failure, as the grafts were not possessed of sufficient vitality for the desired purpose. Still, it is an ill wind that blows nobody any good, and for some time the house-staff luxuriated on the choicest frog legs.—*Correspondence of the Journal of the American Medical Association.*

Washington from a St. Louis Point of View.—Of all the cities in the United States, Washington is more "in touch" with unrighteous covetousness and more out of harmony with the object and purposes of a scientific body than any other with which we are acquainted. The water and air were both bad and pregnant with the bacteria which develop those peculiar ptomaïnes that set up a constant and irresistible intestinal commotion. The party in whose company we found so much of genuine Western sociability was scarcely ever intact because of the tribulations entailed by this state of affairs.—*Weekly Medical Review.*

Society Reports.

NEW YORK STATE MEDICAL ASSOCIATION.

Eighth Annual Meeting, held at the Mott Memorial Hall, New York, October 28, 29, and 30, 1891.

STEPHEN SMITH, M.D., PRESIDENT IN THE CHAIR.

FIRST DAY, WEDNESDAY, OCTOBER 28TH.

THE meeting was called to order by the President, DR. STEPHEN SMITH, at 8.45 A.M.

Suggestions Made by the Committee of Arrangements.—DR. JOHN G. TRUAX read the report of the Committee of Arrangements, which, he said, would refer to some matters not mentioned in the programme. First and most important was the forming of an association in each county which should be in sympathy with the State Association. Membership in one county association should carry membership in others. Next, it was suggested that each member post his Assemblyman and Senator on medical matters which were likely to come before them at Albany. He thought the statute prohibiting a medical man being president of the Board of Health in New York City was an insult to the medical profession and a curse to the people.

Report of the Council.—DR. E. D. FERGUSON read the report. The total disbursements during the year had been $2,248. Balance in the General Funds, $1,085. Balance of the Library and Building Fund, $2.482. Total funds in the treasury, $3.567. The total number of volumes in the liorary was 8,921.

Changes in the Constitution and By-Laws.—The Amendments to the Constitution and By-laws recommended by the Council were all adopted.

The Art of Teaching Medicine.—DR. SMITH chose this subject for his address (see p. 564).

The Use of Chloroform in Labor.—DR. ELBERT T. RULISON, in a brief paper, advocated the use of chloroform in all cases of labor in which there was no contra indication. He spoke of the objection, interfering with the laws of nature, as an old woman's objection, and expressed surprise that physicians to-day allowed their patients to suffer to the end of the labor. Clumsy methods of administration, as by a towel, etc., would account largely for the negative stand taken by many physicians. By the proper use of chloroform the following results would be obtained: 1, no pain, hence no nervous shock; 2, it reduces the number of perineal tears; 3, it shortens the labor, and hence greatly relieves the attendants; 4, child-birth being relieved of its pains, there would be less temptation to criminal abortion. The author praised Battershall's inhaler.

DR. O. C. LUDLOW remarked that some physicians used chloroform in all labor cases, others in none, and both went to extremes. The only ill result which he had observed was a greater amount of oozing after labor and greater tendency to alternate contraction and relaxation of the uterus, making it necessary that the attendant keep his hand longer on the organ in order to secure permanent contraction. A convenient method was to put the chloroform on cotton in a glass.

Words of Caution.—DR. TOWNSEND said he had occasion to use anæsthetics a great deal during the war and since, and he strongly deprecated the general use of chloroform or of any other anæsthetic during labor. Evident, as well as possible unknown, dangers attended such a practice. Among those dangers was post partum hemorrhage. As to inhalers, they produced asphyxia, which meant death if carried far enough. The only safe method was by admitting air. He used a towel for giving both chloroform and ether. It should not touch the face.

DR. MURRAY would not use an anæsthetic in all cases. He used an inhaler, but thought air should be admitted.

DR. DOUGLAS would not have the anæsthesia carried farther than just to relieve pain, believing thereby he would avoid much of the danger.

Forced Respiration—Continued Observations.—DR. GEORGE E. FELL referred to papers which he had read on this subject before, his work having begun four years ago. He had saved eight lives by his method of forced respiration, and others had been more recently saved by physicians in Columbus and elsewhere. Two of his last three had been saved with the use of the face-mask, one with the mask and tracheotomy combined. The author devoted a considerable part of his paper to the question of priority. He claimed that his own was the first systematic work in the line of forced respiration for the saving of life in asphyxia. Professor Wood and some others had suggested certain methods which the author showed would prove impracticable. It should be a great satisfaction to any man to know that a method which he had suggested had been the means of saving a number of lives which must have been lost under all methods previously known.

Preventive Medicine.—DR. HENRY C. VAN ZANDT treated of this subject in a general way, but especially dwelling on the need of educating the public in matters of hygiene and preventive medicine. Might it not be that some of the scourges of the ancients prevailed at present in the form of cholera infantum, etc.? He also suggested that the plagues which afflicted the Egyptians and passed by the Hebrews may have been due to unhygienic and filthy habits and surroundings of the former. The Hebrews, as was evident from the Mosaic laws, had a very good knowledge of preventive medicine

The Theories of Rheumatism.—DR. JOHN SHRADY, in his paper on the above subject, referred to some of the theories which were in vogue among the ancients and which were remarkable for their ingenuity rather than for their rationality. These ancients confined their attention to therapy, as being the most practical side of the question, in view of their knowledge of the conditions of pathology, to say nothing of anatomy, physiology, or the kindred sciences. He maintained that the adherents of the humoral school have at all times held sway, even with the chemical explanations which the subject involved. They stated, roughly but nevertheless truly, that the solution of the problem was to be sought in the blood. Hippocrates and the many followers of the masters contented themselves with the definition that rheumatism was an "acrid defluxion from the brain, contaminating the blood." This view embraced the catarrhal diseases, which Ballonius subsequently specialized into a separate class, and let the awkward term of rheumatism remain as one without any real meaning.

He then touched upon the diet theory and inclined to Dr. Hadden's view, that the meat-consuming individuals and races were, contrary to the popular view, the most exempt from the torment. He took issue with the adherents of the microbic school, claiming that there was no reason why the virus should have a form, as a necessity of its conflict for place. Rather that the law was the one so dominant in natural philosophy, that no two non-homogeneous bodies can occupy the same place at the same time.

Another theory, that rheumatism based upon inflammatory disturbances of nutrition, and which originated venesection measures, once held feeble sway, but yielded its position to the uric acid opinion, which even now might yet be pronounced a dogma. Still, in the present state of our knowledge, this seemed the most reasonable.

Discussion on Acute Diffuse Peritonitis.—DR. ALFRED L. CARROLL read remarks introductory to a discussion of this subject. Five questions were propounded, as follows:

1. What does the normal histology of the peritoneum teach us of its physiological purpose?

2. Do pathological and clinical considerations warrant the separation of cases of acute diffuse peritonitis into different classes, some infective, others not so?

3. What part do micro organisms, or the products of fermentation caused by them, play in the pathogeny of different forms of acute diffuse peritonitis?

4. What are the means of differential diagnosis between various forms of acute diffuse peritonitis, and what the prognosis in each?

5. In what respects are the therapeutic indications in acute diffuse peritonitis modified by the etiological factors? *a*. From wounds, contusions, rupture of bladder or other viscus, or of abscess or aneurism; perforation; intussusception or strangulation; typhlitis; caries of bone; gall-stones; infection in course of lymphangitis. *b*. From fecal impaction; extension from enteritis, hepatitis, or disease of other abdominal viscera; in dysentery or typhoid ulceration without perforation; incidental to paludal or exanthematic fevers, to albuminuria, scurvy, cardiac disease, rheumatism; from exposure to cold and damp; from decomposition of intestinal contents. *c*. In women, from imprudence or exposure during menstruation; extension from pelvic peritonitis, peri-uterine cellulitis, metritis, salpingitis, ovaritis, etc.; from gonorrhœal infection; from abortion; puerperal, extending from metritis, or by septicæmia sequent to abdominal section. *d*. In children, from umbilical phlebitis; intussusception; worms, etc.

After pointing out some of the differences in histological structure between the three serous membranes, peritoneum, pleura, and pericardium, and remarking upon the more elaborate absorbent apparatus present in the latter, he passed to the second question, said that in the vast majority of cases of peritonitis the morbid process began in the sub peritoneal connective tissue of the visceral layer, the virtual continuity of which with the connective tissue stroma of the invested organs, and its lymph-spaces derivative from them, offered facilities for either direct extension of common inflammation or transferrence of septic products, thus affording ground for a distinction between at least two classes of pathic conditions secondary to local visceral disease. But in addition to these there were cases in which the inflammation was excited by mechanical or toxic agents operating immediately upon the peritoneum; others, wherein it arose from lymphangitis or general septicæmia; still others, such as those sometimes called idiopathic, in which the pathogeny was not always discoverable.

Here again the grouping of infective and non-infective was pathologically and clinically manifest. The character of the effusion seemed to depend on the etiological factor more than upon the intensity of the inflammatory process. The plastic form was oftenest seen in peritonitis by extension of aseptic inflammation from subjacent organs, or by "contusion." The exudate might become organized into bands or layers, or its redundant cell elements might degenerate into pus, giving rise in some examples to a secondary infective process, in others remaining laudable, to undergo fatty change and be absorbed, or, losing their liquid part, to be calcified.

The more abundant sero-fibrinous effusions, frequently observed in cases arising from exposure to cold and damp, from fecal impaction, etc., might, under favorable conditions, be rapidly and completely absorbed.

Purulent peritonitis was common from mechanical or chemical irritants, or from putrid infection. In children the proclivity to pus formation in peritonitis was greater than in after life.

Referring to the third question, he said that bacteria might produce a toxic compound; that toxic compounds might also form in the body without the intervention of bacteria, and mentioned the fact that diminished resistance or degradation of the cells facilitated microbial invasion and multiplication. Most of the infective forms of peritonitis were probably caused by the products of bacterial fermentation, and these products might apparently be elaborated by various saprophytic micro-organisms. But there were cases presenting somewhat similar phenomena which were perhaps attributable to endosomatic poisons, generated or accumulated in the disordered tissues.

The author then pointed out some difficulties in the way of diagnosis, and some facts bearing on the prognosis. The latter, he said, was serious in infants in inverse ratio to the age.

The relation of the etiological factors to treatment was then taken up. It was evident the author did not believe in blindly applying the so-called opium treatment to all cases. He said that even in other than surgical cases this "bugbear of peristalsis" was inconsistently dreaded, for when tympanites occurred peristalsis ceased.

Some indications were mentioned for heart tonics, for laxatives, for turpentine stupes and hot fomentations, rectal alimentation, etc.

Non-infective Peritonitis.—Dr. E. D. Furguson read a paper bearing on Questions 2, 4, and 5. While it would be accepted as proved that certain infective agents caused acute diffuse peritonitis, the converse was not so clear—*i.e.*, that acute diffuse peritonitis might arise from non-infective causes, for to prove a negative in this instance would hardly be possible. But while not able to assume with certainty that this affection could arise from non infective sources, still, in the present state of our knowledge of pathology, it seemed probable that it could have such an origin, for the fact that mechanical irritation would produce a variety of the inflammatory process practically settled the question. Clinically cases were found that did not correspond to the usual ideas of an infective peritonitis.

In the case of a child he was consulted with reference to doing laparotomy for the relief of peritonitis. There had been about a day of invalidism. There was some distention of the abdomen, walls tense and board like, abdominal tenderness and pain, fever, etc., but from the rather sluggish condition of the mental faculties, the absence of any probable causes for a diffuse peritonitis of such rapid development, absence of constipation, and presence of regurgitant vomiting of a thin mucus, he ventured the opinion that it was not a case of peritonitis, but that there was a production of poisonous alkaloids going on in the bowels beyond the capacity of the liver to serve as a graveyard for such compounds; that it would result in profound effect on the nerve-centres, a diffuse interstitial and parenchymatous hepatitis, with a resultant increase of pressure in the gastro-intestinal veins, hæmatemesis of the "black vomit" variety, and death. The autopsy verified his diagnosis. He had previously had a similar case. While some cases, like one of perforation of the gut and operation, which he related, at at some portion of or during the entire course simulated diffuse peritonitis, yet autopsy had failed to show it. Nevertheless it seemed probable that the development in the bowels of a toxic agent capable of producing such morbific conditions might, under certain circumstances, allow of the passage of a toxic agent through the coats of the bowel, so as to cause a peritonitis.

Referring to laxatives and opium, he said: When the peritoneum is roughened by inflammation or other cause, peristalsis must cause mechanical irritation, and in addition it would tend to the spreading of irritating products, as pus, etc. In so far as the "opium splint" will lessen this source of irritation it is logical, but if there is ground to conclude that the origin of the irritant is within the bowel, and that constipation would favor either its production or absorption, then a cathartic that will tend to produce efficient evacuations with the minimum mechanical disturbance is indicated.

Dr. Heneage Gibbes, of Detroit, sent a paper on the first question. In the peritoneum, he said, we have a thin, delicate membrane, forming in its ramifications various folds. It possessed a considerable amount of strength and a varying amount of elasticity, according to

the function which the particular parts had to accomplish. The frame-work was composed of white fibrous tissue arranged in bundles, which interlaced and gave it the necessary consistency, and among these bundles were net-works of elastic tissue, which varied in amount according to the elasticity required in the part. On both surfaces of the free peritoneum was a single layer of large flat cells. Among these were longer cells, with more sinuous outlines, which belonged to lymphatic vessels running in the substance of the membrane. Among the covering cells were small openings called stomata, which communicated with the lymphatic vessels. Running through the substance of the membranes were blood vessels and nerves. In adults, membranes were masses of adipose tissue, and in young animals collections of small round cells forming cords around the vessels and small nodules. In some animals other structures were found. Embryologists now seem to consider the epithelium on the peritoneum of connective-tissue origin, yet from certain pathological evidences, the author said, this does not seem probable. Balfour and Hertwig regarded it as of hypoblastic origin. If this view were correct the epithelium might have some secretive function. The lymph passed from the blood-vessels on to the surface of the peritoneum in sufficient quantity to keep it moist and reduce friction to a minimum. This lymph had another important function, which was to nourish a considerable portion of the elements which went to make up a serous membrane. In return it received various excrementitious matters. There were two channels by which the blood was returned to the arteries, the venous, with a special arrangement for replenishing it, and the lymphatics by which the serous portion of the blood was returned to the arteries loaded with the products of cell-metabolism. The peritoneum was capable of exerting its functions under various conditions which deviated greatly from the normal. This was shown by the large amount of foreign noxious material which could be absorbed and removed from the peritoneal cavity without causing any inflammatory action in the membrane. He had injected various fluids into the peritoneal cavity without producing any appreciable effect on the animal. He had also injected fluids containing pure cultivations of various micro-organisms into the cavity without producing any effect, while the same amount of fluid injected into the systemic circulation blocked up several of the capillaries in the glomeruli of the kidneys, causing inflammation and breaking down of small areas of the cortex. It seemed to him the lymph which exuded into the peritoneal cavity had some action on noxious material by which it was deprived of its virulence, provided the quantity introduced were not too large. Material which coagulated like blood would, by blocking the stomata, prevent the absorbent action, and inflammation would take place.

Dr. Victor Vaughn, of Detroit, sent a paper which opened with the remark that, notwithstanding the fact that the bacteriological studies of acute diffuse peritonitis had not been altogether harmonious and conclusive, he would attempt to answer the question concerning the relation of micro-organisms to this disease. He wished, however, to reserve the right to make such modifications of his answer in the future as further researches might demand. Although germs were found abundantly in the various forms of exudate occurring in this disease, no one species or kind was found invariably present. Bearing on this statement he quoted Bumm, Predöhl, Boisleux, Netter, etc. Peritonitis might be induced experimentally in animals with any one of a number of germs, as the staphylococcus pyogenes, bacillus pyocyaneus, and the so-called bacillus peritoniditis (Powlowsky), bacterium coli commune, etc. At least one germ, the bacterium coli commune, which normally grew in the healthy intestine, might induce peritonitis after passing into the peritoneal cavity. This was a point of much practical importance, for it was probably true that actual perforation was not necessary to the passage of this germ through the intestinal walls, that this might occur when the mucous membrane became necrotic from simple inflammation or was destroyed by non-perforating ulceration. While it was true that peritonitis might be experimentally induced by the injection of culture of certain germs into the peritoneal cavity, the success of these experiments was influenced by certain conditions. The more important of these conditions were: 1, the presence in the cavity of chemical irritants; 2, the state of health of the peritoneum. Experimentally an aseptic peritonitis might be induced by chemical irritants.

Dr. Harold C. Ernst, of Boston, discussed the subject of etiology as stated in the first and second questions. Pathological considerations by themselves, or distinct from bacteriological, furnished no trustworthy data upon which to base an opinion, and we must therefore look to the results of experimental work for material upon which to found our conclusions. In doing this it was not possible to consider peritonitis as a process separated by any line except that of locality from similar changes that might go on in other parts of the body, and from this point of view peritonitis must he looked at in the light of the enormous body of facts that had been collected in late years as the result of the newer methods of research. This knowledge taught us several things in regard to acute inflammatory or suppurative lesions that must, for the most part, be taken as proven. Of these the most important appeared to be the final disposition that had been made of the theory of a spontaneous generation. The inquirer could not find sufficient ground for the separation of different clinical forms of peritonitis even into septic and specific, much less for the setting off of a class of cases as aseptic. It certainly seemed as if it were proven that all forms of peritonitis occurring in human beings were due to the activity of bacteria or their products and that all of them were to that extent specific and septic also. This did not deny the possibility of the existence of a process closely resembling a non-suppurative peritonitis and due to the action of some irritant or caustic chemical.

Dr. George E. Fell also discussed the subject of normal histology of the peritoneum. It taught us, in part, that the membrane was provided with a lubricatory function which permitted the various contained organs to move in accordance with their purpose without hindrance, the functions to be carried on without waste.

Dr. John Cronyn endorsed the remarks of Dr. Furguson. Bearing on the question of metastatic inflammation of the peritoneum, he mentioned the case of a young man whom he saw with Dr. Rochester, in whom suddenly there developed severe pain over the abdomen, which Dr. Cronyn believed to be due to the metastatic tuberculosis from the lungs (for the patient had pulmonary changes), while Dr. Rochester thought it a case of indigestion. The patient died after some days, and marked miliary tuberculosis of the peritoneum was found. He recommended the use of three to five grains of quinine when giving opium, as exhancing its beneficial effects.

Restitution in Cases of Small Perforations of the Intestine and Peritoneum.—Dr. Charles A. Leale related a case of pistol shot wound of the abdomen, sustained ten years before the patient's death. There had been evident perforation of the peritoneum and intestine, the ball having entered near the umbilicus and been cut out beneath the skin at the back. Absolute quiet was enforced, the abdominal wound sealed, hot poultice applied over abdomen which relieved pain, non fecal producing food given, and the patient was well within six weeks. The autopsy, ten years later, showed no change except slight diminution in the calibre of a gut where it had been perforated.

Dr. W. H. Flint read a paper, discussing *b* of Question 5. It might be stated as a general principle that the indications in the treatment of diffuse acute peritonitis arising from inflamed neighboring tissues looked, first to controlling the peritoneal inflammation, and second to re-

moving the primary causative conditions. In acute peritonitis from fecal impaction the indications were to first control the inflammation, and then relieve the impaction. Injections and cathartics employed first were liable to do harm. The patient should be kept at rest, opium administered, vomiting checked, warm applications made to the abdomen, the strength sustained, and when the inflammation had been controlled the impaction might be overcome. Where the peritoneal inflammation was due to paludal fevers, control the latter by injections of quinine. Erysipelas claimed energetic local treatment from the beginning. In albuminuria, scurvy, and rheumatism treat the general and local condition at the same time.

Dr. John Shrady confined himself to the discussion of the differential diagnosis, and spoke of the great awe in which the peritoneum was once held. He attributed the recent-day triumphs of abdominal surgery to its greater boldness, which furnished more cases and therefore better statistics. Asepsis, of course, played its part, but perhaps in the optimistic way of giving more confidence. What was not done could not be expected to be followed by results especially beneficial, in other words, it was a reversion to the old maxim, "Nothing venture, nothing have."

Dr. B. A. Watson read a paper bearing chiefly, yet in a general way, on the indications for surgical treatment. In ruptnre of the bladder an immediate operation was called for. The difficulty of making an exact diagnosis sometimes led the surgeon to hesitate until too late in cases of penetrating wounds, etc. In strangulated hernia great harm had been done by taxis. An attempt should be made to reduce the hernia under ether, the head down, and this failing an operation should be performed. In intestinal obstruction the great difficulty again was in making a prompt diagnosis.

Indications for Treatment of Acute Diffuse Peritonitis in Obstetric and Gynecological Cases.—Dr. George T. Harrison discussed *c*, under Question 5. Referring to prophylaxis, he said menstruating girls should be cautioned to use only aseptic napkins. During labor and abortion great care was called for to avoid sepsis.

One should discriminate between septic and non-infective peritonitis. The first demanded imperatively an operation. The abdominal cavity should be cleansed of all foreign matter, strewed thinly with finely powdered iodoform, and close the abdominal wound. The two forms most difficult to deal with were the septic and gonorrhœal. In the beginning of the peritonitis a laxative sometimes was useful, while later it was liable to do harm. Opium was nsually indicated to relieve pain, but often the ice-bag, or coil, applied over the abdomen, had given such relief that opium could be discontinued.

In anæmic cases a flannel should separate the rubber bag containing ice from the abdomen. As to septic peritonitis following laparotomy, he had often seen the abdomen reopened, but the patients always died. It was certainly true that if in the future success was to follow operation in diffuse acute septic peritonitis, early intervention would be imperatively demanded.

Dr. William McCollom quoted a recent paper, which discussed peritonitis from the specialist's or surgeon's stand-point, which ridiculed the view that the disease was ever idiopathic. Dr. McCollom could see no reason why peritonitis might not be idiopathic since pleurisy might be so. He referred to experience in Vermont, where most of the cases followed exposure to wet and cold in previously healthy men. He would class the greater proportion of cases as idiopathic, if it was proper to so speak of cases originating in exposure to cold. His treatment by opium had been much more successful than that of his preceptor, who administered cathartics, and thereby caused his patients to writhe in agony. He quoted the arguments of Alonzo Clark, and of Watson (England), favoring the opium treatment—arguments which, although used over forty years ago, appealed to reason just as forcibly to-day.

Aseptic Plastic Peritonitis.—Dr. Nicholas Senn, of Chicago, thought some confusion had arisen as to the meaning of aseptic plastic peritonitis and infective peritonitis. A plastic process in the peritoneum took place in consequence of traumatic irritation, and should no longer be called an inflammation. Here the process did not tend to spread, it remained localized, was limited. A good illustration was seen in perforations of the stomach. It was entirely different in septic peritonitis, for here the primary cause tended to multiply and spread the disease.

Pressure Ascites.—Dr. Senn also recited a case with formation of large amount of ascitic fluid without apparent cause, resembling a large hydrocele, in which condition there was no adhesion of peritoneal surfaces. This could hardly be called a peritonitis. It was cured, in the one or two cases related, by continued drainage. The explanation offered was relief of pressure.

Dr. H. O. Marcy also related a case of ascites with no apparent cause except that the man drank excessively; was cured by tapping and prolonged drainage. The great majority of cases of peritonitis were, he thought, infective. Cases of tubercular peritonitis operated upon by him had been benefited.

Dr. Strong cited cases and warmly advocated the use of opium in peritonitis. Its success would depend upon the boldness with which it was administered.

Peritonitis in Children.—Dr. J. Lewis Smith read a paper discussing this phase of the subject. Peritonitis, he said, spared no age. It had been seen in the newly born, and even in fœtuses. It was most common in the newly born among the tenement-house class, where there was greatest exposure to sepsis. Sepsis often entered at the umbilicus. He did not doubt peritonitis might, like nephritis, result in children from taking cold. It was often due to extension of disease from neighboring organs. He saw at least one case of intussusception in children yearly, and this, of course, was likely to excite peritonitis.

Some cases of peritonitis in children had arisen from extension of the gonorrhœal process from the vagina, uterus, and tubes, to the peritoneum. Diagnosis and treatment other than snrgical also received the author's attention.

Differential Diagnosis.—Dr. E. G. Janeway related some cases illustrating difficulty of diagnosis in peritonitis. There might be in children tenderness all over the abdomen, distention, local pain, temperature, yet have a reflex condition instead of septic peritonitis. Some cases of pleurisy or pneumonia simulate peritonitis. Reflex neuralgias connected with disturbances of the liver, perhaps associated with jaundice, sometimes simulated peritonitis. Biliary colic might be mistaken for peritonitis, fever sometimes being present in these cases Nor could we depend alone on the presence or absence of liver flatness in diagnosticating perforation of the bowel. As to the spleen being the source of irritation in peritonitis, it was difficult to make out the size of that organ during the distention and pain attending peritonitis.

Address on Surgery.—Dr. Nicholas Senn, of Chicago, delivered the address (see p. 557).

Second Day, Thursday, October 29th.

Resolutions on the death of Dr. Abram Du Bois were read by Dr. Hubbard and adopted.

Representation in the American Medical Association.—The following was unanimously adopted:

Whereas, The constitution of the American Medical Association is such that no medical organization in the State of New York is entitled to representation in that body except the New York State Medical Association:

Resolved, That our delegates to the meeting to be held at Detroit, 1892, be instructed to call the attention of the American Medical Association to this fact, and to urge that the Committee of Registration be directed not to

register delegates from the State of New York except they have credentials from the New York State Medical Association.

Resolved, That this Association approves the protest already entered before the Judicial Council of the American Medical Association against the appointment of an officer from the State of New York who is not a member of the New York State Medical Association.

Notes on the Treatment of Tuberculosis.—Dr. Warner, of New York, had recently made a study of tuberculosis in Europe, and had used tuberculin in nine cases at the Charity Hospital, New York. The treatment in most of them was continued two or three months. Of the nine cases, three became worse under treatment; two improved; two improved much; two practically recovered. He thought tuberculin was an agent which early in tuberculosis might retard the progress of the disease, prolong life, and in some instances exert a curative influence. Its action might be aided by inhalations of creosote. The cuspidor should be set aside, and a paper cup substituted which could be burnt.

Dislocation and Fracture of the Vertebræ.—Dr. Charles W. Brown, in a paper on this subject, related a case of dislocation of the vertebræ at the fifth and sixth dorsal, in a man who sustained the injury in a railway accident. Paraplegia resulted. He made use of a pulley in reducing the dislocation, which was accomplished with some difficulty. Improvement took place at once, and the man finally was able to walk with the aid of a cane, but died about eight months later in a hospital in Washington, having certain paralytic symptoms, but only a meagre history could be obtained.

Where fracture took place, one should cut down and remove bone which might necrose or cause pressure, etc.

Dr. Robert Newman related two cases of dislocation. Reduction in the first was accomplished as described by the author, and plaster of Paris applied. No motion was possible in the lower extremities for more than six months, when he directed the splint should be removed and galvanism applied to the spine, positive pole above. Improvement, and soon, practically, complete recovery took place.

Dislocation of the Astragalus.—Dr Douglas Ayres related the histories of two cases of forward and outward dislocation of the astragalus, with the mode of reduction and result. The histories were preceded by a statement of the comparative rarity of the accident and the difficulty of effecting reduction. The patient was given chloroform, and the operator, sitting between his legs, grasped the instep of the affected limb with the left hand, the heel with the right, and while an assistant held the thigh he made extension, and at the same time endeavored to press the bone forward and inward. By persistent effort he at last engaged the bone under the tibia. Use was made of the foot as a lever. The author did not believe, however, that it was possible to formulate an exact course, applicable to all cases, owing to the various complications which might arise. His patients began to use the limb after some weeks, and went on to full recovery.

Dr. J. W. S. Gouley had seen seven cases of dislocation of the astragalus, the last one in September of this year. The mode of reduction was chiefly by persistent manipulation, very little force being used, chloroform being the anæsthetic. Of the seven, four were reduced, two could not be reduced owing to numerous other complications; in one excision was performed for the same reason.

Dr. E. M. Moore thought that on applying the splint after reduction it was important to place the foot at right angles, one reason being that if anchylosis should take place the foot would be in best position. He had treated two cases, effecting reduction in the last one easier, because relying on manipulation and traction, without the pulley employed in the first instance.

Dr. Senn said it was necessary in complicated cases to carry out most careful after-treatment in order to prevent anchylosis.

Larvæ of Dipteræ in the Human Intestine.—Dr. Homer O. Jewett exhibited larvæ of dipteræ passed with the fæces in two different cases. One case occurred in a man, school-teacher, who had had annoying sensations in the abdomen, and when the larvæ were passed had an itching sensation at the anus which caused him to examine the evacuation and then found the larvæ. His habits were cleanly, the water-supply was from a driven well. The other case occurred, about the same time, in a girl, living some miles distant from the first patient. They were strangers to each other; there could be no collusion between them. The girl's mother had given her a "worm medicine," and in the discharges into a mug these larvæ were found. Some more were discharged at another passage. This family was also cleanly, and obtained their water from a driven well of thirty-five feet.

Dr. Alfred S. Carroll had examined the larvæ; had found a record of only two other cases of their appearance in the human intestine. There were only four or five dipterous flies the larvæ of which had the peculiar tails seen in this example, and the larvæ of two were so much alike that they could hardly be distinguished the one from the other until the change into flies had taken place. They might have been ingested on vegetables.

Monstrosity.—Dr. Jewett also presented to the museum a monstrosity, consisting of two female children united at the side and chest. They were born before his arrival, and he was told had shown brief signs of life. Soon a boy child was born, and lived.

Case of Rupture of the Diaphragm (?).—Dr. S. T. Clark related a case in which according to the symptoms he made a diagnosis of rupture of the diaphragm at the anterior superior angle of the œsophageal orifice, with consequent laceration of the artery at that point and disturbance of the phrenic nerve. The injury had been sustained after heavy lifting; immediately there was pain at the ensiform cartilage, pallor, etc. These attacks recurred two or three times when the man violated instructions and ate improperly, causing, it was supposed, distention of the stomach and reopening the wound, permitting hemorrhage and causing displacement of the heart. On July 2d there was rather sudden relief, and the heart was found returned to its normal position, due, it was explained, to sufficient absorption of the clot to permit of its release.

Discussion on Alienism.—This discussion had been arranged by Dr. Judson B. Andrews, and was limited to the causation of insanity.

Heredity and Environment.—Dr. Andrews read a paper on this part of the subject. He would not, as some did, deny the force of heredity, yet it was proper to question the extent of its influence. That there was an heredity of physical characteristics was patent to the most superficial observer; but the force of heredity in mental peculiarities, he said, was not so striking. The drift of thought to-day was, that not the disease, but want of resisting power, was transmitted. To give heredity as the efficient cause would be to ignore in a given case all the diseases and debilitating influences with which life might be surrounded. Statistics had been advanced in argument, but they varied and were more or less unreliable. It was generally believed twenty-five to thirty per cent. of cases of insanity showed some form of it in the ancestry. But heredity alone did not produce insanity. There must be some exciting cause, as impairment of the general health, physical or mental overwork, sexual and other excesses, etc. In early life the parents should look to the environment of the child in whom there might be supposed tendency to insanity, later the individual must become responsible. Considering the manner in which many people live, eating and drinking wrongly, undergoing extreme exposure, etc., the wonder was more did not become insane.

Selection of a Mate.—By way of prevention nothing

was more important than the selection of a companion from a healthy family, of even temper, without known tendency to insanity. It might be objected that advice to this effect would not be followed by those about to mate, but that fact would not change nature's law.

Traumatism and Shock.—Dr. H. M. Hurd, of Baltimore, read a paper on traumatism and shock as causes of insanity. Besides injuries of the skull, resulting in depression of bone, injury of vessels of the brain, and concussion, he classified sunstroke (he preferred to call it heatstroke) under the head of traumatism. As a result of excessive heat the blood-vessels became paralyzed, the current was slowed, the heart beat less rapidly, death in extreme cases resulted from obstruction in the lungs or pressure upon nerve-centres. Passive congestion of the brain might go on to active inflammation, there might be convulsion, delirium, unconsciousness, and death. But in cases not fatal, the power of heatstroke in the production of insanity could not be overestimated. In many instances where the patient apparently recovered from the first effect, there was still such a change set up in the brain as in time to lead to actual mental disease. In its leading characters this form of insanity resembled the traumatic forms. There was the same suspicion and apprehension; there might be delirium or maniacal excitement. The asylum records contained the histories of many cases of chronic insanity dating from sunstroke. Epileptic insanity had a similar origin in many cases which had come under his observation. Progressive dementia seemed to be the rule where there was injury to the brain, but where there was secondary meningitis there were periods of excitement, delusion, suspicion, finally the brain symptoms became allied to those of paretic dementia.

The author gave some examples of change mentally bordering on insanity, following some time an injury to the head. There was no doubt but what insanity developed later in life in cases where, as children, the patients had suffered an injury to the head. The mental change was apt to make its appearance at the physiological epochs in life. Some of these persons developed epilepsy, but the majority did not.

In traumatic insanity the most constant mental symptoms were delusions of suspicion and apprehension. Instances were given of a tendency to vice and crime following trauma. In his experience in asylums about three per cent. of all cases of insanity seemed to be due to trauma.

Arrest of Development and Diseases of Infancy as Causes of Insanity.—Dr. E. N. Brush, of Pennsylvania, read a paper on this phase of the subject. Besides the many cases of insanity in persons in whom imperfect development was apparent, showing some cause operating in childhood, there were cases in which, although there might be no apparent want of development, the history failed to show a period at which there had not been a neurotic tendency. Comparatively recent studies had been made of the palatine arch in the insane and idiots, in whom it was frequently found deformed. In less than one-fifth of the ordinary population the arch was found deformed, while among idiots less than a tenth had a normal palate, and in over two-thirds it was deformed. This deformity was apt to be connected with some imperfect development or change of the bones of the cranium or brain.

Many things might be said of the diseases of infancy and childhood producing insanity.

Bodily Diseases and Senility as Causes of Insanity.—Dr. P. M. Wise sent the paper, which was read by Dr. Andrews. According to a collection of cases of insanity made by Dr. Major, bodily diseases contributed to the cause in twelve to fourteen per cent. Bodily diseases acted secondarily in creating the psychosis through defect in blood-supply, excessive nerve energy through peripheral irritation, extension of disease from lower to higher centres, etc. Post-febrile insanities contributed a small proportion of cases of insanity, smaller than formerly. The pathological process which left the brain disordered after fevers or acute inflammatory processes was unquestionably vascular primarily; secondly, inability to throw off degraded tissue and renew the element. The relation of phthisis to insanity was not well defined. The conditions of hospital life tended to develop phthisis; less so at present, however, than in the past, when hygiene received less attention. Phthisical insanity was characterized by delusion of suspicion. Heart disease was not uncommonly a direct physical cause of insanity, independently of other predisposing conditions. The anæmia resulting from aortic stenosis and the congestion or œdema following mitral disease were explanatory of not a few cases.

Arterial capillary fibrosis, or endarteritis, was frequent in the insane when admitted to hospitals. The manifestations of insanity in these cases appeared to indicate a lowered nutritive condition, and could not well be confounded with the uræmic insanity of Bright's disease, which, in his experience, was seldom met with in hospital insane.

Insanity occasionally followed an attack of nephritis; rheumatism be the sole cause; gout also might produce a mental state bordering on insanity. But of bodily diseases syphilis exerted the largest influence in the production of insanity. Myxœdema, sunstroke, and other conditions were mentioned.

The popular belief that diseases of the sexual organs bore a common and close relation to insanity was not thought to be well founded. The connection, when it existed, was often only incidental. There was, he said, no uterine psychology. He had not yet seen a recovery from insanity which was even remotely due to gynecological treatment. It was seldom where insanity had followed childbirth that there was not an hereditary or acquired tendency. Extension of disease from the cord to the brain, producing insanity, constituted a small ratio, yet in hospitals one met with many cases of disease of the cord in connection with insanity. It was not infrequent for general paresis to follow tabes, and in such cases there was probably a like cause. Epilepsy, chorea, catalepsy, etc., often had insanity supervene. Epilepsy was a cause in about eight per cent. of hospital cases. Loss of special senses might be followed by insanity.

The author thought it might be said that generally the psychology of bodily diseases had been a neglected subject. Speaking of senile insanity, while the disease did occur at times in the aged, yet as a rule the mental changes were not so great but what they could be accounted for by the retrograde process which took place in the aged. It was a tendency to blotting out of the faculties. He hoped physicians would exercise discretion, and not, taking advantage of the new law, overload the State institutions with this class of cases.

Syphilis and Intemperance as Causes of Insanity.—Dr. G. Alder Blumer, of Utica, read this paper. Insanity, he said, was due to a conspiracy of conditions, and the best that one could do was to name the arch-conspirator. Brain syphilis was not uncommon. Could it produce general paresis? Some said it produced true general paresis; at any rate it often produced something closely resembling it. The percentage of cases in which syphilis was present in the insane had been stated differently by observers. In 257 cases of general paralysis the author had found that 66.5 per cent. were syphilitics. But it was a question in these cases how much alcoholism, sexual and other excesses, which were common, contributed to the disease. When one spoke of intemperance he entered upon dangerous ground. Some exaggerated this influence, yet it was undoubtedly great. To the credit of America it could be said that the proportion of cases of insanity attributable to intemperance was lower than in Europe. Forty five per cent. of the cases in Vienna (where beer was much used) were attributed to intemperance.

Causes of Insanity Peculiar to Women.—Dr. W. D. Granger, of Mount Vernon, read the paper. His con-

clusions were: 1, Men and women suffer almost equally from insanity; 2, sex modifies somewhat the disease, as does each individual, each cause, etc.; 3, that the general causes of insanity are the same in men and women; 4, that special conditions peculiar to each sex occupy a narrow field in the total causation of insanity; 5, that the general causes are always more or less in operation at times when special causes operate; 6, that causes peculiar to women—the climacteric period, pregnancy, childbirth, prolonged lactation, uterine disease, menstrual irregularities—are to be found, one or more, in almost every woman, yet few suffer insanity; 7, that special causes operate essentially in the same way as do general causes, by producing anæmia, malnutrition, shock, loss of sleep, etc.

Gunshot Wound of the Brain.—Dr. John Cronyn related, in a paper bearing the title "Subjects of Interest, Medical and Surgical," two cases, the first of which was one of gunshot wound of the brain. The patient was a boy. The ball entered the forehead on the left side, above the orbit; he was supposed by the parents to be dead. When Dr. Cronyn probed the wound the instrument entered the brain, came in contact with the bullet, caused a click, and the ball moved backward. This was followed by twitching of the limbs, respiration, and signs of returning life. The third day the boy became conscious. He seemed not to know what had happened. The right arm and leg were paralyzed. Within three months he was able to be up; the paralysis was much better, he made great efforts to speak. Before the accident he had been able to read, write, and cipher, but on recovery he had lost all recollection of the alphabet and had to learn it over again, but his capacity for calculation had improved tenfold. In due time there was complete restoration to health; one could scarcely recognize where the ball had entered, and when he presented the boy at a medical society doubt was expressed whether he had ever sustained a gunshot wound of the head. Nine years and a half after the first accident the boy was struck on the opposite side of the head, died in a few days, and the coroner found the old bullet sacculated in the posterior portion of the left hemisphere, lower in the brain mass than the point of entrance. Careful search was made for the track of entrance, but no trace of it could be found. The case was of interest psychologically, and as showing the tolerance of the brain.

Recovery from Locomotor Ataxia.—Dr. Cronyn's second case was one of locomotor ataxia in the second stage, with cure following an attack of erysipelas of the face and head. The symptoms of locomotor ataxia in the second stage were recognized by several of the hospital staff as typical. The man continued under treatment about a year, without benefit, when the attack of erysipelas set in after exposure to cold. He was violently delirious about four days. After recovery from erysipelas it was noticed that he could walk without a cane, there was no ataxia, he remained well and in the hospital for three years, was exhibited to students, and had continued well since returning to work. Dr. Cronyn asked to what the cure was due? There had been no history of syphilis, and the treatment had not been antisyphilitic. He suggested that the erysipelas may have extended down the cord, producing congestion, local extra-nutrition of the sclerosed lateral columns, with restoration of function. Of course the diagnosis would be doubted, yet it had been confirmed by several neurologists.

At the evening session Dr. Charles Stedman Bull read a paper on "Tumors of the Orbit and Neighboring Cavities," and Rev. William C. Bitting delivered an address on "Biblical Medicine," after which a collation was served.

Third Day, Friday, October 23d.

Orton Prize Essay.—The committee reported that ten essays competing for this prize had been submitted, and after due deliberation it had been decided to award the prize to the one on "Impure Air and Ventilation of Private Dwellings." The envelope containing the author's name had not yet been opened. The essay will appear in the "Transactions."

Mental Therapeutics.—Dr. Henry D. Didama in this paper quoted instances contained in ancient and modern history, some of which showed that mental suggestion or mental action had alone effected a cure; in some there was combined mental and physical action, some it was difficult to classify. Among the several classes might be mentioned the looking upon a stone which was said to have the power of curing all diseases, animal magnetism, carrying a horse-chestnut, hydrophobia cure, etc. There were many cases in which it was difficult to say just how much the cure was mental and how much physical, or due to the action of a drug upon the body. In proportion to the ignorance of a people was charlatanry successful.

Dr. H. O. Marcy in discussing this paper said that if he were going to offer a prize it would be for an essay on a subject like that so ably dealt with by Dr. Didama, in order that the public might be educated out of their ignorance and wooed from their superstitious beliefs regarding disease and its cure.

Address on Gynecology.—Dr. A. Palmer Dudley read the address. After a brief review of what gynecological surgery had accomplished in the past ten years, and expressing the conviction that the balance rested largely on the side of profit, he took up one kind of failure which had occurred in a certain per cent. of the cases.

Fecal Fistulæ Following Laparotomy.—The nature of the failure referred to was the occurrence after laparotomy of a fecal fistula which, in some cases at least, caused the patient greater annoyance than the disease for which an operation had been performed. It was all the more important to reflect upon and study these cases, because the condition was one which might be obviated by care in the breaking up of adhesions and freeing the appendages for removal. A fecal fistula had formed in two cases out of two hundred consecutive laparotomies in his own practice, and he had been able to collect the record of seventy-four altogether. In sixty-four of these, extensive adhesions in the pelvis and injury to the gut while breaking them up, overlooked at the time, were the prime cause of the accident. The next most frequent cause was the indiscreet or improper use of the drainage-tube. It was used in many instances where there was no need for it. Gauze was safer than the glass tube. In only 13 of the 74 cases was the drainage-tube not used; in 26 the accident was attributed to the tube by the operator. A third cause was the use of catgut in intestinal surgery. While the author was a strong advocate of catgut generally, yet in suturing the intestine it was unsafe, since a small strand had to be used and the fluids in the intestine were likely to act upon it and cause it to give way before union had been obtained. In the 74 cases Tait's operation, tubercular peritonitis, and ovarian cyst occupied the first, second, and third places. The location of the opening in the gut was not known in many cases.

The author gave the history of one of his own cases in detail, it being one of fistula which had already formed after an operation in California. He opened the abdomen, closed several openings into the gut, just above the cæcum, and dissected out the fistulous tract. The patient did well for some days, and then fecal extravasation again took place, due to giving way of the sutures in the larger of the intestinal perforations. Death resulted. If by medical and simple procedures a fecal fistula could not be closed, laparotomy should be performed, and the tract and opening into the intestine be dealt with according to the indications in the individual case.

Optic Neuritis as a Form of Peripheral Neuritis.—Dr. Alvin A. Hubbel, of Buffalo, read the paper. Among the causes of this form of optic neuritis might be mentioned injury, contiguous inflammation, growths causing

pressure and irritation; certain substances or poisons, as alcohol, lead, arsenic, and bisulphide of carbon; certain diseases, of which diphtheria was a marked example; also typhoid fever, malarial fever, etc. In short, certain poisons and certain diseases might cause an inflammation of all classes of peripheral nerves, those of special sense as well as those of motion and sensation; the cause was widespread and common, and the treatment identical.

Puerperal Eclampsia—Report of a Desperate Case.—Dr. George E. Fell related the case. Coma and convulsions came on at the seventh month. Three physicians had been called before he arrived. Hydrate of chloral and diaphoretics were used. He effected delivery. The uterus was irrigated. Albumin was plentiful in the urine. Chill and fever appearing about the fifth day, the uterus was again thoroughly flushed. The patient recovered. The uric acid diathesis was very marked in this case, and doubtless had been present before, and he asked what influence it may have had in causing the puerperal eclampsia. A ptomaine, leucomaine, or some toxic agent would probably be found to be the cause of puerperal eclampsia, as of other conditions. He thought his patient would have died had the uterus not been irrigated, and he queried whether this treatment might not save many other cases.

Dr. Fell also related the case of a woman who had a pneumonic complication and in the course of a few days inhaled over one thousand gallons of oxygen. Whenever it was discontinued marked symptoms of dyspnœa returned. There was ultimate recovery.

Disease of the Knee-joint in the Convalescent Stage.—Dr. T. M. L. Chrystie, of New York, presented in this paper arguments to show that while during inflammation the knee should be kept at absolute rest, after the inflammation had subsided motion with certain restraining conditions was necessary in order to keep up the integrity of the joint—to keep the component structures in a healthful state. But during convalescence from disease the muscles and structures about the joint were in what had been called a devitalized state, and if use were permitted without certain restricting conditions injury would result which would tend to repeat itself with every attempt to walk. An example of this was given in the case of a man whose limbs appeared to be normal except that one was shorter than the other. This led to a lateral jerk in the knee on the side of the short leg, and the injury constantly repeating itself while walking, a synovitis was the result. A cure was effected by lengthening the limb with a cork sole applied to the shoe. Dr. Chrystie then presented and described an apparatus to be worn during convalescence from knee joint disease.

Typhoid Fever in Children.—Dr. William D. Garlock, the author, thought the germ-theory certainly applied to typhoid fever. Having given the sources of the germs, and mentioned the symptoms as they occurred in children, the author tried to account for the difference in the course of the disease as it appeared in children and adults. In children there was less frequently ulceration of Peyer's patches, consequently of perforation and of hemorrhage. The fever was milder and shorter in children, to be accounted for by the fact that there was less septic absorption from Peyerean ulcers. For the same reason there was less pain and gurgling in the abdomen. The eruption was often absent. There was greater liability to nephritis and bronchitis in children. The sensitiveness of the vaso-motor system in children, shown in the ready blush, etc., would account for certain peculiarities of the disease as manifested in them.

Dr. Alfred L. Carroll admitted the obscurity of the symptoms of typhoid fever in children in many cases, which made the diagnosis difficult. He believed he had sometimes made the diagnosis of typhoid when malaria was the real trouble. He thought there was quite a number of cases of infantile remittent, although some authors doubted the existence of this disease.

Dr. Stephen Smith remembered a case in which Dr. Alonzo Clark was present in consultation, and called it typhoid fever, saying that he had hardly seen a case of remittent fever, which the other consultants thought this one to be. Yet he admitted not having made an autopsy in the typhoid of children, and could recall but one case in which the ulcer of Peyer's patches had been found.

Carcinoma of the Breast.—Dr. Joseph D. Bryant read a brief paper, which was intended to be a discussion of a paper by Dr. Wyeth which was read by title. Dr. Bryant confined his remarks to the conditions most likely to contribute to good results. The main points were that patients should early recognize the presence of any tumor, immediately consult a competent physician, means be taken to make an exact diagnosis at once, and, carcinoma being recognized, make free excision, going if possible at least an inch outside of apparently healthy tissue, then remove the lymphatics of the axilla whether seemingly enlarged or not. Recurrent manifestations of the disease should be met in the same prompt manuer.

Lateral Curvature of the Spine Associated with Hernia.—Dr. S. E. Milliken, of New York, read a paper with this title. In connection with his duties at the hospital for the Ruptured and Crippled he had often had his attention drawn, while examining young people for hernia, to a commencing lateral curvature which had not yet attracted the parents' attention. It might be that the theory of a lack of strength of muscles, offered by some to account for the one condition might account for the occurrence of both hernia and lateral curvature in the same individual. It would be necessary, however, in offering the same theory in explanation of both conditions, to account for the greater frequency of hernia in boys and of lateral curvature in girls. He was convinced that a badly fitting truss had something to do in the causation of spinal curvature in some patients.

The author made some observations upon treatment, especially mechanical and gymnastic. An attempt had been made at a combination of the two, but he thought it would always prove impractical, for they were completely antagonistic to each other. Where a splint was used he preferred the plaster-of-Paris jacket. An early diagnosis was important, and the parents or a physician should see that the child maintain as constantly as possible a proper posture, exaggerating the same during gymnastic exercises before a mirror.

Dr. E. M. Moore said he had tried the old method of using the perineal band with straps attached, with a view to correcting lateral curvature, but found, as others probably had, that owing to pain in the perineum the patient would not stand sufficient pressure to be thus made to prove of any benefit. Thinking, however, that the principle was correct, and that restraint such as a splint would enforce was objectionable, he set to work to devise a means by which the subject would be led to correct his position, say ten thousand times a day, and thereby in time overcome his deformity. In carrying out his idea he made use of the long spring which had its connection with the foot, and straps were so passed as to make pressure upon the projecting points caused by the curvature, and while not restraining motion it was sufficiently annoying to the patient to lead him to try to get out of its way and therefore to straighten up. In the few cases where he had applied it, good results had been obtained, and he regarded it as the best apparatus which he had seen, yet he had not published its description.

Dr. Thomas Manley also made some remarks, and impressed the importance of healthful food and hygienic surroundings in connection with other treatment.

Congenital Imperforate Rectum.—Dr. E. D. Ferguson read a paper on this subject, relating a case operated upon successfully with another physician, and describing methods applicable to the four different classes of cases, namely, those in which there was simple occlusion by membrane or skin, those in which there was absence of the anus, the canal ending in a pouch or series of pouches, those in which the proctodium formed but failed to con-

nect with the rectum, and those in which there was entire absence of rectum and anus. One should seek to make an opening for the canal in the normal position for the anus, and if the case were found to belong to the fourth class, perform colotomy.

Dr. Judson B. Andrews was elected President.

Correspondence.

MATERNAL IMPRESSIONS AGAIN.

To the Editor of the Medical Record.

Sir: Being a firm believer in maternal impressions, I have been not a little interested in articles on that subject which have appeared of late in your journal. It seems to me, however, that in the communication which appeared in a recent issue, the writer would have made points for "our side" by leaving out his first case.

Will it not be too much to ask "the opposition" to believe that one rosy dawn was responsible for five albinos, and they not all in succession?

The following are some cases which have come under my notice and have served to strengthen my belief in maternal impressions:

Mrs. M. W——, on realizing that she was pregnant, was nearly mad with rage; upbraided her husband; threatened to kill the child, etc.

The child was born at full term with no more than the usual amount of difficulty. It proved to be an idiot.

Mrs. S. J—— had precisely the same experience and with a like result. She, however, became reconciled to child-bearing and has since been delivered of four children, all of whom are of average intelligence.

Mrs. H. G——'s brother had his left arm amputated. She called at his house to see him, and while there a secondary hemorrhage of the stump commenced. When the child which she was carrying at the time was born it was minus a left arm.

Mrs. S——, while yet a short time pregnant, saw her neighbor's child which had been struck in the head by a car. The right superior maxilla was crushed in and the inferior maxilla sustained a comminuted fracture of the right side, giving the face a peculiar one-sided appearance. Mrs. S——'s child when born had the same peculiar asymmetrical features.

I will make no comment on these cases, they speak for themselves.

Physician.

New York, October 20, 1891.

New Instruments.

a temple of Jupiter on the spot, with its staff of priests, is well known; and the relics that have turned up near it attest its uses to have been similar to those of the present hospice. A discovery of importance has just been made in its vicinity—a bronze statue in excellent preservation of Jupiter himself. Its artistic value is very great; its height forty centimetres. At the same time other treasure trove was brought to the surface, including a number of medals and a statuette of a lion measuring sixteen centimetres, also of fine workmanship. These are now the property of the monks, and will attract to the hospice public more able to keep them in funds than the proper recipients of their kindness. Sad to relate, the revenue of the monastery, heavily drawn upon by the travellers (from 16,000 to 20,000 annually) who throw themselves on its bounty, are diminishing, the contributions left by these comfortably accommodated guests being miserably below what, in the majority of cases, they can afford. The heroism of the monks should be remembered by the well-to-do holiday visitor. They begin their career at the age of eighteen or nineteen. After fifteen years' service the severe climate has made old men of them. For eight

soft rubber catheter, has induced me to devise a simple glass instrument which has done away with all of the objections which usually appertain to those hitherto in use.

It consists essentially of a glass tube, slightly bent to suit the urethra, having the perforation in a well-rounded end; and at the distal extremity a good flange for the purpose of attaching a piece of rubber drainage-tube five inches in length. The glass tube is exactly two and one-half inches long. The attachment of the drainage-tube occupies one-quarter of an inch, thus leaving a maximum length of catheter two and one-quarter inches. This will thoroughly empty any bladder; at the same time the point of the instrument only enters the bladder to a position where it cannot impinge against its walls. I have taken pains to emphasize this element of length, as one of the chief advantages of the instrument would be lost if it were lengthened beyond the dimensions given. The drainage-tubing serves as a convenience only, and may be removed at will. While not in use I fill the catheter with an antiseptic liquid and retain it by attaching the distal end of the tubing to the bladder end of the catheter. This keeps the inside of the instrument surgically clean. Of course proper sterilization of the catheter should be secured before using. I have put this in the hands of all my nurses with the greatest satisfaction in the results. The woodcut is an exact representation—one-half size.

Mr. M. J. Breitenbach has manufactured the catheters accurately. The W. F. Ford Instrument Co. and others also keep them in stock.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 25, 1891, to October 31, 1891.

Ball, Robert R., First Lieutenant and Assistant Surgeon. Granted leave of absence for one month, with permission to apply for an extension of one month.

Maus, Louis M., Captain and Assistant Surgeon. Relieved from duty at Whipple Barracks, Ariz. Ter., and ordered to Fort Apache, Ariz. Ter., for duty.

Richards, Charles, Captain and Assistant Surgeon Relieved from duty at Fort Logan, Col., and will report in person to the Commandant of the Military Prison, Fort Leavenworth, Kan., for duty.

Official List of Changes in the Medical Corps of the United States Navy for the week ending October 31, 1891.

Harvey, Henry P., Surgeon. Ordered to Receiving Ship St. Louis.

Flint, James M., Surgeon. Detached from Smithsonian Institution, and ordered to the Miantonomah.

Heyl, T. C., Surgeon. Detached from Receiving Ship St. Louis and to wait orders.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 31, 1891.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	61	12
Scarlet fever	79	15
Cerebro-spinal meningitis	2	3
Measles	28	3
Diphtheria	97	32
Small-pox	0	0
Varicella	4	0
Pertussis	3	4
Erysipelas	1	0
Mumps	0	0
Rötheln	0	0

The Influence of Sex in Otitis.—Dr. Loewenberg, of Paris, discusses the influence of sex in what he calls the "laterilization" of ear disease. After referring to the view generally held by otologists, that the left ear is more liable to be attacked alone, or to be attacked first and to suffer more severely when both ears are affected, he says that he has for a long time past been struck with the fact that, while deafness is more common on the left side in men, the same does not hold good in the case of women. From statistics of 3,000 cases (not including diseases of the concha and external meatus) which have come under his own notice, he shows, in the first place, that the male sex is more subject to ear disease than the female, there having been 1.790 of the former to 1,210 of the latter. Among those in whom only one ear was affected, there were 478 men and 311 women. The right ear alone was affected in 212 men and 167 women; the left alone in 266 men and 144 women. Deafness existed in both ears in 1,074 men and 737 women. Among this number the right ear was the more deaf of the two in 427 men and 340 women, the left in 647 men and 397 women. Deafness was equal on both sides in 238 men and 162 women.—*British Medical Journal.*

Hypnotism in Surgery.—A female patient under the care of Mr. Hare, in Ancoats Hospital, Manchester, was suffering from anchylosis of the elbow-joint of long standing, for which excision was performed. In spite of early passive movement after the operation, the joint again became immobile in an extended position. The patient was then hypnotized by Mr. Mursell, the resident surgeon, and was told that she could bend the arm without pain. This she did, and the suggestion remained effective for several days. She was again hypnotized and the suggestion repeated, with the effect of procuring perfect power of motion in the joint.—*Lancet*, September 26, 1891.

Leprosy in Siberia.—Two English ladies, Miss Marsden and Miss Field, are living in Siberia, where they have devoted their lives to the care of the outcast lepers in that bleak and desolate region.

India-rubber Heels are recommended by a French military surgeon in order to prevent repeated slight shocks to the nerve centres, to which he believes the sensation of fatigue is largely due.

Tape-Worm.—A correspondent writes to know if there is any better remedy than male-fern or pumpkin seeds for the cure of tape-worm.

A Penalty for Not Believing in Vaccination.—It is said that fully 25,000 deaths occurred in one of the recent epidemics of small-pox in Guatemala, but notwithstanding this frightful mortality and the frequency of small-pox scourges, the Government has taken no pains to introduce any scheme of vaccination, and the state is without any vaccination laws at all. In this respect Guatemala is far behind some of the neighboring Central American countries. A medical society in Guatemala has taken up the subject and will endeavor to persuade the Government to adopt proper sanitary laws.

Bearing with Him.—A new terror of courtship has been developed in the case of an Indiana brunette. For some days she has suffered from a supposed attack of pleurisy, but when Dr. S. F. Bordman was called in he found that one of the young lady's ribs was fractured. After much questioning the girl blushingly admitted that her best beau had inflicted the injury while giving her his usual tender embrace before parting on his last visit. The occurrence of the accident was marked by a sharp pain in the side, a "catch in her breath," and a sudden relaxation of her hold.

The First Colored Female Physician.—Dr. R. J. Stanton, of this city, writes: "I wish to correct the impression that the first female colored doctor belongs either to the South or to the West. She belongs to our own State of New York. In 1876 Miss Sarah M. Loguen, daughter of the late Bishop Loguen, and a relative of Fred. Douglass, was graduated from the Syracuse Medical College."

Dr. Robert Reyburn, of Washington, D. C., writes: "Sir: Allow me to correct an error in the Medical Record of October 17, 1891, page 488, which states that 'Dr. Consuela Clark, a colored lady of Cincinnati, O., has practised medicine since 1886.' This seems to claim for Dr. Consuela Clark that she was the first colored female graduate in medicine in the United States. The Catalogue of the Medical Department of Harvard University, which I send herewith, shows on page 25 that Miss Eunice V. Shedd graduated in medicine in 1877. On the same page will be found the name of Miss Nannie W. Stafford, who graduated in 1878. The Medical Department of Harvard University has graduated colored female physicians at almost every commencement since 1880, and was among the earliest of the medical colleges to adopt the three-years graded course, having adopted it in the session beginning 1879–1880."

A Fraudulent Canvasser.—A swindler is travelling in the West who represents himself as agent of the St. Louis Library Association, and obtains subscriptions for leading periodicals at reduced rates. Of course all he receives is clear profit, as no magazines are forthcoming. He is particularly attentive to physicians, hosts of whom are complaining of the swindle. He is described as having reddish hair, is five feet eight inches tall, is about thirty-five years of age, weighs about one hundred and sixty pounds, and is a glib talker. He gives all sorts of receipts, and mystifies by his apparent care in his attention to details.

his position, say ten thousand times a day, and thereby in time overcome his deformity. In carrying out his idea he made use of the long spring which had its connection with the foot, and straps were so passed as to make pressure upon the projecting points caused by the curvature, and while not restraining motion it was sufficiently annoying to the patient to lead him to try to get out of its way and therefore to straighten up. In the few cases where he had applied it, good results had been obtained, and he regarded it as the best apparatus which he had seen, yet he had not published its description.

Dr. Thomas Manley also made some remarks, and impressed the importance of healthful food and hygienic surroundings in connection with other treatment.

Congenital Imperforate Rectum.—Dr. E. D. Ferguson read a paper on this subject, relating a case operated upon successfully with another physician, and describing methods applicable to the four different classes of cases, namely, those in which there was simple occlusion by membrane or skin, those in which there was absence of the anus, the canal ending in a pouch or series of pouches, those in which the proctodium formed but failed to con-

The American Public Health Association was organized in 1872 for the purpose of inaugurating measures for the restriction and prevention of contagious and infectious diseases, and for the diffusion of sanitary knowledge among the people. The growth of the association and the work it has accomplished more than justify its existence. Its membership has been augmented from year to year until it now constitutes the largest and strongest sanitary body in the world, and embraces in territorial extent the United States, the Dominion of Canada, and the Republic of Mexico. Under the impetus given by its work, state and local boards of health and sanitary associations have been organized, sanitary publications increased, and hygienic knowledge widely and extensively diffused. The qualifications required for membership are a good moral character, an interest in hygiene, and the indorsement of two members of the association. Application blanks may be obtained from the secretary, Dr. Irving A. Watson, Concord, N. H.

Syphilitic Reinfection.—At a recent meeting of the Kieff Medical Society Dr. Boroffski reported the case of a man who had been treated for a syphilitic chancre in 1885. In November, 1890, he entered the Kieff Hospital for treatment of syphilis. He stated that three weeks after an impure connection he noticed an ulceration along the corona of the glans, which was diagnosed by the physician whom he consulted as a hard chancre. Soon after the inguinal and cervical glands became swollen, and at the end of seven weeks he had a general syphilitic eruption covering the entire body. Examination showed the presence of mucous patches on the mucous membrane of the cheeks, tonsils, and palate.

The Hospice of the Great St. Bernard.—This asylum for the Alpine wayfarer (7,609 feet above the sea-level) is said to have been founded A.D. 962 by St. Bernard, of Menthon, while, according to some authorities, it rose a century earlier, under Charlemagne. Neither saint nor emperor is likely to make good his claim, as the archives of the hospice have been completely destroyed in two successive conflagrations. But, like other Christian institutions, it had undoubtedly a pagan predecessor. The Romans on the self-same spot built a temple to the Pennine Jove, and that, in turn, occupied the site of a still earlier shrine of prehistoric antiquity. The truth is, the Alpine passes were in common use from the remotest ages—the Christian world treading the same route which had been trodden by the Romans, who also availed themselves of the track made by the aborigines. At its highest point the tutelary deity had his place of worship, and this was served by the local priesthood, who rendered assistance to the distressed or ailing traveller and received votive tributes in return for its good offices. The existence of a temple of Jupiter on the spot, with its staff of priests, is well known; and the relics that have turned up near it attest its uses to have been similar to those of the present hospice. A discovery of importance has just been made in its vicinity—a bronze statue in excellent preservation of Jupiter himself. Its artistic value is very great; its height forty centimetres. At the same time other treasure-trove was brought to the surface, including a number of medals and a statuette of a lion measuring sixteen centimetres, also of fine workmanship. These are now the property of the monks, and will attract to the hospice a public more able to keep them in funds than the proper recipients of their kindness. Sad to relate, the revenues of the monastery, heavily drawn upon by the travellers (from 16,000 to 20,000 annually) who throw themselves on its bounty, are diminishing, the contributions left by these comfortably accommodated guests being miserably below what, in the majority of cases, they can afford. The heroism of the monks should be remembered by the well-to-do holiday visitor. They begin their career at the age of eighteen or nineteen. After fifteen years' service the severe climate has made old men of them. For eight or nine months out of the twelve they see none but the poorest wayfarers, when the cold is intense, the snow lying deep, the danger from storms incessant and fearful. Their sole companions are the dogs, whose keen scent has guided them to the snow wreath under which the buried traveller has so often been rescued and brought to life—dogs like that noble fellow "Barry," who saved forty men in his time, and who now, carefully stuffed, adorns the museum at Bern. The poet laureate of the monks, we are proud to say, was a medical man, the late Dr. David Macbeth Moir, of Musselburgh (the "Delta" of *Blackwood*), whose sonnet beginning "Where these rude rocks on Bernard's summit nod," is one of the finest in our language, and, translated into Ovidian elegiacs by Dr. Samuel Butler, Bishop of Lichfield, forms the gem of the "Arundines Cami."—*The Lancet.*

A Backslider for Malthusianism.—Mrs. Annie Besant, since she has begun to receive communications from the Mahatmas, has recanted her advocacy of the doctrines of Malthusianism. She still sees evil in large families, but thinks man should avoid this material evil by the spiritual remedy of marital restraint, rather than by the material one of mechanical prevention.

Syphilis in South Africa.—According to the annual report of the Albany General Hospital, Grahamstown, South Africa, syphilis is very prevalent in that district, nearly one-sixth of the patients admitted during the year being cases of that disease. The number, however, is steadily decreasing, and since the Contagious Diseases Act has been put in force in the seaport towns the disease has assumed a milder form. Of the sixty-three patients admitted only nine were whites, one female and eight male. Among the important and rare cases, other than syphilitic, were four of hydatids of the liver, three of which were cured by operation, and one died from rupture of the hydatid cyst into the peritoneal cavity before admission to the hospital.—*Hospital Gazette*, September 26, 1891.

Post-Graduate Instruction in Germany.—The medical faculty of the University of Greifswald has established a system of post-graduate instruction which promises to be popular, as upward of eighty German and foreign physicians are in attendance at the first course.

The Association of German Alienists, at its recent session in Weimar, passed a resolution approving of the new law to repress drunkenness, but deprecated the clause referring to the punishment for intoxication. It was recommended that habitual drunkards be sent to State institutions, where they should be under constant medical care.

The Source of False Hair.—The English consul at Canton says that eighty thousand pounds of human hair have been exported from that city during the past year, and that it comes mainly from those who have died of contagious diseases, mendicants and criminals.

Some Things Ordered at the Druggist's.—A well-known Philadelphia pharmacist has recently received the following written orders for medicine: A dose of castor-oil for a child aged fifteen. Be sure and send enough to work her good. One dozen two-ounce quinine pills; one bottle honeatta water; a boo gee; one box of Brandreth's pills, sugar quoted. Please send enough appecac to throw up a four months old baby; two five-grain blue mask pills; ten cents worth partisapated chalk.

Nux Vomica in Cardiac Failure.—Dr. A. Bowie (London *Lancet*) reports two cases of cardiac failure in which death seemed imminent, that were speedily relieved by small doses of the tincture of nux vomica every half-hour for four doses, then every hour. He considers it the most valuable remedy that we have.

Dangerous Pets.—A French scientist declares that the lomestic pets of the world carry at least thirty per cent. of the common contagious diseases from house to house.

Malformation of the Heart.—A remarkable case of congenital malformation of the heart has been recorded by C. Cipriani. The subject, a male, lived to the age of twenty, having been markedly cyanosed all his life. There was transposition of the lungs, and the heart lay on the right side. This organ consisted of only two chambers—a lower conical one with a rudimentary septum at the apex, whence proceeded the pulmonary artery (with stenosed orifice) and the aorta. The upper chamber was somewhat narrowed where it was connected with the lower one, and at this spot was a rudiment of a valve. Neither this valve nor those of the pulmonary artery and aorta were competent. The liver occupied both hypochondriac regions, and its left lobe was much more developed than the right. The spleen was hypertrophied, and had a horizontal furrow across its middle portion, while in the vicinity were three other spleens, each the size of a fowl's egg. The stomach was very small and atrophied. The duration of life under these circumstances is not the least singular feature of the case.—*The Lancet.*

Preparing the Skin for Antiseptic Operations.—Dr. F. W. Langdon, of Cincinnati (*Lancet-Clinic*), calls attention to the value of benzin as a solvent of oily secretions in the preparation of skin areas for antiseptic operations. An agent that can penetrate and disinfect the pores and follicles of the region to be operated upon has advantages not possessed by any of the watery solutions in common use.

The Influence of One Fever on Another.—Under this caption, Dr. H. Noble Joynt, of the Bradford Fever Hospital, gives some observations which he has made in the course of his wide experience in fever cases.[1] He remarks: "It is the daily experience, and indeed the bane, of every fever hospital physician to see a patient suffering from one fever, develop a second which has been incubating in his system before admission; or when convalescent, contract a fever from some other patient in spite of all precautions." Thus he has seen "mulberry rash of typhus and the rose spots of enteric well developed at the same time; the erythema of scarlatina forming a brilliant ground for the vesicles of varicella, the dark maculæ of measles and rötheln, and the rose spots of enteric."

Such observations are by no means new, but it has been the custom to deny that they are due to the presence of two distinct diseases in the individual at the same time, but to assume that these appearances are more apparent than real, and merely accidental manifestations of the original poison.

The dictum that but one infectious disease can exist in an individual at a time, has secured an almost universal acceptance, and has even dominated workers in original investigation, and yet it must be admitted that it stands only on clinical ground, and therefore is no more worthy of credence than the opposite view.

Now that it has been established that diphtheria is a local process, which produces its systemic effects through the poisons elaborated at the seat of the lesion, and absorbed therefrom, there can certainly be no objection, even theoretical, to the view of the old clinicians that diphtheria may be engrafted upon any of the infectious diseases.

Certainly the chemical poisons of diphtheria can be absorbed from a mucous surface by a patient affected with an infectious disease, as readily as the medicines administered can be absorbed, and there is no reason why their superadded effects should not be exhibited. When it has been shown satisfactorily just how many and what micro-örganisms can produce the disease or diseases known clinically as diphtheria, it will be time enough to determine whether the false membranes developed in the throat in scarlatina, typhoid, and other diseases, are truly diphtheritic or not.

Why are not many of the symptoms of typhoid fever due to the absorption of poisons from the intestinal canal, intoxication complicating infection?

Concurrent varicella and scarlatina has recently received some attention at the hands of the French.

We have recently seen a child, who in the course of whooping-cough, developed a typical enteric fever, during which the characteristic whoop ceased, to return on the cessation of the fever.

It is admitted that clinical evidence alone is not sufficient to establish the concurrence of two diseases, neither is it sufficient to disprove their concurrence. The apparent concurrence of two infectious diseases is not common, but to deny that such an actual concurrence is impossible is going farther than exact observation warrants.—*Journal of the American Medical Association.*

The Treatment of Senile Gangrene.—In a recent issue of the *Deutsche Medicinische Wochenschrift*, Professor Haidenhain presents his views on this subject, which are based on a careful study of twenty-five cases of senile gangrene of the lower extremity, the majority of which occurred in diabetics. It is a well known fact that this form of gangrene is characterized by especial severity, so that the author's rules for treatment are worthy of careful consideration. He advises that as long as the gangrene is confined to one or two toes we should abstain from surgical intervention, and wait for a line of demarkation to form. Local antiseptic measures and elevation of the limb are all that is required, and we are especially warned against the detachment of the gangrenous portions with the scissors and forceps, which tends to increase the inflammation. If the gangrene spreads to the dorsum or sole of the foot, we should adopt Hutchinson's recommendation and amputate at the thigh, making as small skin flap as possible. An extensive experience has shown that amputation below the knee in these cases is apt to be followed by gangrene of the flaps, which, if it does not lead to a fatal termination, renders a second operation necessary. If high amputation is deferred until the development of fever and suppuration the prognosis becomes the more unfavorable. While it is true that a successful result has sometimes been obtained by amputating below the knee, the weight of testimony is decidedly in favor of the high operation.—*Inter. Jour. of Surgery.*

To Empty a Distended Bladder.—To empty at once a distended bladder, is to expose the patient to the danger of a vesical hemorrhage; it is necessary to desist as soon as the urine does not escape in a jet, but falls in driblets, drop by drop.

THE SURGICAL TREATMENT OF PYLORIC STENOSIS, WITH A REPORT OF FIFTEEN OPERATIONS FOR THIS CONDITION.

BY N. SENN, M.D., PH.D.,

PROFESSOR OF PRACTICE OF SURGERY AND CLINICAL SURGERY IN RUSH MEDICAL COLLEGE; ATTENDING SURGEON TO THE PRESBYTERIAN AND EMERGENCY HOSPITALS; SURGEON IN CHARGE OF ST. JOSEPH'S HOSPITAL, CHICAGO, ILL.

(Continued from page 563.)

Author's Cases of Gastro-enterostomy for Malignant Disease of Pylorus.—The following cases of gastro-enterostomy were made by myself during the last three years. In all of them the indication for the operation was an advanced carcinoma of the pylorus. All of the patients were greatly emaciated, and in two of them the general debility was so great that the operation was not advised, and was performed only at the urgent request of the patients and their friends. The perforated decalcified bone plates were used in all operations in uniting the intestine with the stomach. At first dry plates were used, but after having met with two accidents, caused undoubtedly by the hygroscopic nature of the material, these were abandoned, and since using moist plates, kept in an antiseptic solution, no case of pressure necrosis has occurred.

I have made it a rule that the patient should abstain from taking food by the stomach for at least twenty-four hours prior to the operation, and rely during this time and a few days after the operation entirely upon rectal alimentation. The following description of the operation answers for all the cases.

The evening before the operation the stomach was washed out by the syphon-tube and again just before the anæsthetic was administered. For the last irrigation a five per cent. solution of salicylate of soda or Thiersch's solution was used. In all of these cases the incision was made through the median line and extended from near the ensiform cartilage to the umbilicus. The opening in the stomach was made parallel to the long axis of the organ and at least an inch and a half distant from the margin of the tumor. A continued suture of fine silk catgut was applied around the whole circumference of the opening, both for the purpose of arresting hemorrhage and preventing bulging of the mucous membrane. The opening in the intestine was made first and the plate introduced and sutures adjusted and the loop retained in the lower angle of the wound, covered by a warm compress. The large curvature of the stomach near the pyloric orifice was then drawn sufficiently forward into the wound to make the incision and introduce the plate. When everything was ready for adjustment, the parts around the visceral wound were carefully disinfected, dried, and the serous surface lightly scarified with an ordinary needle over a surface corresponding to the size of the plate; the visceral wounds were then brought opposite each other and a number of fine silk sutures, embracing only the serous and muscular coats, were applied behind the posterior margins of the plates and tied; the middle lower suture was now tied, while an assistant approximated the two openings; the end sutures were next tied, and lastly the anterior middle. The sutures were all cut short and ends buried. During the tying of the sutures it is necessary to exercise caution that the margins of the visceral wound are well embraced by the plates all around. As in these cases the weight of the intestine exerts considerable tension, I have taken the precaution to apply a superficial continuous suture anteriorly after tying the four sutures so as to approximate the serous surfaces over the anterior margins of the plates. The necessary preparations being made, with good assistance the operation can be finished in from twenty to thirty minutes. Usually on the third day small quantities of peptonized milk and beef-tea were given at short intervals and solid diet during the second week.

CASE I.—Male, aged sixty-five. Symptoms of pyloric stenosis for one year. Emaciated to a skeleton; œdema of legs; unable to retain food of any kind for more than a few hours. The patient was so anæmic and prostrated that he was only partially anæsthetized. During the operation the pulse became almost imperceptible, and brandy had to be administered subcutaneously, with lowering of head, and hot applications externally. An hour after the operation the pulse was stronger than before it was commenced. Rectal feeding; only slight rise in temperature on second day; no pain. On the third day small quantities of liquid food by the stomach. The heart's action gradually failed and the patient died of marasmus five days after the operation. The autopsy showed that the plates were still *in situ*, adhesions firm and opening patent. No peritonitis. In this case the carcinoma was circular and limited to the pylorus. Anastomosis just below the duodenum. The intense suffering had made the patient desperate, and although the nature of the disease and the probable outcome of the operation had been fully explained to him, he begged to have it done, with a perfect understanding that at best it would afford only temporary relief. I am quite confident that the operation did not shorten his life.

CASE II.—Male, aged forty seven. Duration of disease eighteen months; obstinate vomiting; great emaciation and œdema of legs. Contour of tumor could be readily mapped out by percussion and palpation. Tumor adherent to under surface of liver; enlargement of lymphatic glands. In this case the anastomosis was again made just below the duodenum. No untoward symptoms after operation. At the end of the first week solid food was allowed. No vomiting. At the end of the third week an abscess formed in the upper part of the healed incision, in the contents of which the plate ligatures were found. A gastric fistula formed, through which food escaped almost immediately after it was swallowed. This closed in less than two weeks, after which the patient improved in strength and gained in weight. He retained and digested all kinds of food. Improvement continued, so that he was able to walk short distances and to take long drives. At the end of three months after the operation he commenced to fail, and died two weeks later of progressive marasmus. Unfortunately no autopsy could be obtained.

CASE III.—Male, aged thirty-five. Symptoms of pyloric stenosis for six months. Tumor discovered four months ago, rapidly increasing in size. Considerable emaciation and cachectic appearance. Tumor involves nearly one-third of anterior wall of stomach and the entire pylorus. Glands of omentum infiltrated. The first loop of intestine which came within reach was united with the anterior wall of stomach in the usual manner. Sutures of abdominal wound removed on the eighth day. Until this time no untoward symptoms, although the patient had taken liquid food for several days. The day

following, obstinate vomiting occurred; the plates, very much softened and greatly reduced in size, were ejected. The stomach was repeatedly irrigated, but vomiting continued until the patient died, three weeks after the operation. Autopsy: Abdominal incision united throughout; omentum, stomach, and intestines adherent to abdominal incision. Anastomosis perfect at a point eight feet below pylorus. Intestine between pylorus and artificial opening enormously distended As the opening was large enough to admit two fingers, it was difficult to understand what had caused the obstruction. The pyloric orifice was large enough to admit the tip of index-finger. Fluid could not be forced from the stomach into the bowel below the new opening. Injection through the duodenum was made with the same negative result. On close examination it was found that the intestine at the point of anastomosis, probably on account of the great length of the part between the stomach and the new opening, had become flexed at the point where it was attached to the stomach, and the two limbs were adherent to each other for four inches. This bending of the bowel had formed a spur, opposite to the opening in the stomach, by the apex of the concave side of the bowel, and this spur acted like a valve, closing the opening in the distal part of the bowel when water was injected into the stomach or duodenum.

This case taught me that it is unsafe to follow the advice given by Luecke and others, to seize the first presenting loop for the anastomosis, as by so doing it is possible to grasp a loop of intestine which corresponds to the lower portion of the small intestines, as in this case. If this is done, we not only exclude permanently too great a portion of the intestinal canal from the processes of digestion and absorption, but a similarly unfortunate mechanical difficulty at the new opening may be created, as has been described above.

Lauenstein recently reported a case of gastro-enterostomy where the autopsy revealed that the new opening was made near the ileo-cæcal region. In making a gastro-enterostomy it is important, for the reasons just cited, to follow the advice of Hahn or of the author and search for the duodenum, which, when found, can be readily recognized by its short and fixed attachments, and to make the new opening in the upper part of the jejunum as near as possible to the duodenum.

Case IV.—Male, aged forty-three. Has complained of stomach difficulties for a year. During the last two months obstinate vomiting an hour or two after meals. Tumor as large as a child's fist; movable. Emaciation and marked anæmia; glandular infection behind the stomach. Anastomosis made just below the duodenum. Very little pain, and no other symptoms until the tenth day, when he vomited several times. Stomach washed out twice, four hours apart, and food by the stomach discontinued. No vomiting after this, and after two days a liquid diet ordered. At the end of the second week could digest all kinds of solid food, which caused no distress. On the thirteenth day fragments of both plates were found in one of the stools. Patient has gained in flesh, and after four weeks presented a great deal better appearance than before the operation. Patient survived the operation four months, and finally died of marasmus.

Case V.—M. S——, German, laborer, aged thirty-eight, was admitted into Milwaukee Hospital, December 3, 1888. Carcinoma not hereditary in the family. In June last, patient first experienced a distressed feeling in the stomach a few hours after meals, attended by occasional attacks of vomiting, which occurred at intervals of several days and always afforded temporary relief. As the disease progressed the quantity of fluid ejected from the stomach became larger, and always contained fragments of food eaten several days before. The attacks of vomiting became more frequent and gastric digestion more impaired. About two months ago progressive emaciation set in, the patient has lost thirty-five pounds in weight since the beginning of his illness. The pain has been intermittent in character and occasionally quite severe. At the time of admission the patient was greatly emaciated, the skin dry, and of a dark, almost bronze, color. A well defined tumor is readily detected a little below the normal location of the pylorus. This tumor is quite movable and ascends and descends synchronously with the respiratory movements. Irrigation and insufflation indicate that the stomach is greatly distended. A large quantity of partially digested food is removed through the stomach-tube. As the patient's condition was becoming more insufferable from day to day, and the treatment pursued had afforded no relief, he was exceedingly anxious to avail himself of whatever benefit might follow an operation. As his strength had been failing very rapidly for the last two weeks, and as marked anæmia was present, I was fearful that the disease had resulted in almost complete obstruction of the pylorus, and had probably extended to one or more of the surrounding organs. Gastro enterostomy was performed December 16th. Immediately before the operation a subcutaneous injection of one sixtieth of a grain of atropine was made, and he was given at the same time two ounces of whiskey in warm water per rectum. On opening the abdomen the dilated stomach presented itself at once in the wound. By pushing the organ toward the left side the pyloric portion was made accessible to inspection and palpation. A carcinoma extending from the pylorus to near the middle of the anterior wall of the stomach was readily mapped out. The disease was much more extensive than I had reason to believe from external examination before the abdomen was opened. Manual exploration revealed what I had suspected—extension of the carcinoma from the posterior surface of the stomach to the head of the pancreas, and numerous carcinomatous lymphatic glands behind the stomach and in the great omentum. As the anterior wall of the stomach was so extensively infiltrated it became necessary to make the incision for the communicating opening with the small intestine nearer the cardiac than the pyloric orifice. The part of the intestine selected was the junction of the duodenum with the jejunum. Duration of operation about thirty minutes.

The patient recovered satisfactorily from the immediate effects of the operation, and although he vomited twice during the evening the pulse and temperature were noted as normal the following day. On the second day a slight tympanites developed, at the same time the patient complained of pain at the site of operation. Rectal injections were relied upon exclusively in stimulating and supporting the patient. Although the temperature remained normal until the morning of the fifth day after the operation, tympanites and pain remained as conspicuous symptoms, and the pulse became more rapid and feeble. The bronzed color of the skin, so marked before the operation, assumed a deeper hue from day to day. On the morning of the fifth day the thermometer registered 97° F. under the tongue, but toward evening the temperature increased to 101° F. The next morning the temperature reached 104° F., and at noon the patient expired. The autopsy revealed a minute perforation at the upper border of the approximation-plates. Dry plates were used in this case, and these had become much softened and thickened, and remained *in situ*. Adhesions between stomach and intestine quite firm. Peritonitis limited to the upper portion of the abdomen. Nearly half of the stomach on pyloric side involved by the carcinoma. Pyloric obstruction almost complete. Pancreas extensively infiltrated. As only a few auxiliary superficial sutures were used in this case it appears probable to me that during the violent attacks of vomiting, soon after the operation, a limited separation of the approximated viscera occurred, and that the peritonitis, which was the immediate cause of death, was due to this cause.

Case VI.—A farmer, aged sixty-nine, came under my observation at the Milwaukee Hospital, March 28, 1888. No hereditary predisposition to carcinoma or tuberculosis in his family. He was an industrious man, and in pos-

session of good health until March, 1882, when he had an attack of dyspnœa, which he attributed to fatty degeneration of the heart. A similar attack occurred during the following month, which this time was believed to have been caused by dyspepsia. From this time on he experienced, at different times, weight and a sensation of fulness in the stomach an hour or two after meals. In January, 1889, he first discovered a tumor in the region of the stomach; at the same time digestion became more impaired, so that he could eat and retain only the lightest articles of food. His general health failed rapidly, and before he entered the hospital his body weight was reduced from one hundred and fifty to one hundred and fifteen pounds. For the last ten days stomach-feeding had to be suspended almost completely on account of the pain and distress that followed the eating of small quantities of the blandest kinds of food. Patient is very anæmic, ankles œdematous, pulse 80 to 90 per minute, and very soft and compressible. Tumor in pyloric region about the size of a small orange; movable. After inflation the outline of the large curvature of the stomach could be seen and felt two inches below the umbilicus, while the tumor did not change its relative position to the anterior abdominal wall. Although the patient and friends were fully informed in reference to the probable outcome of an operation, in view of the enfeebled condition of the patient, gastro-enterostomy was performed at their urgent request, March 31, 1889. Elaborate preparations were made for the operation, for the purpose of preventing collapse. Atropia and whiskey were administered as in the preceding case. The abdomen was opened as usual in the median line, and by retracting the margin of the wound on the right side, the carcinomatous pylorus was brought at once into the wound. The disease had passed beyond the serous coat, and at some points fungous masses could be seen and felt on the surface of the tumor. Adhesions had formed between the growth and the under surface of the liver, and the head of the pancreas appeared to be incorporated in the cancerous mass. The disease involved about four inches of the pyloric end of the stomach. Numerous carcinomatous glands in the great omentum and behind the stomach. An anastomotic opening was established between the stomach, about two inches from the border of the tumor, and near the great curvature and the small intestine, about three feet below the pylorus, by the aid of a large pair of soft plates of decalcified bone. The serous surfaces between the plates were freely scarified, and the action of the plates enforced by superficial interrupted sutures posteriorly, and the continued suture along the anterior border of the plates. Although the operation did not require more than thirty minutes, toward its close the patient's condition became critical—pulse almost imperceptible, profuse clammy perspiration, and pupils widely dilated. Under the influence of stimulants administered subcutaneously and per rectum, and the external application of heat, the pulse improved temporarily, but collapse again appeared, and the patient died two hours after completion of the operation.

Case VII.—German laborer, aged thirty-two, was admitted into Milwaukee Hospital, April 8, 1889. His digestion had always been good until nine months ago, when he first experienced pain in the region of the stomach, especially an hour or two after a hearty meal. Three months later a swelling was detected to the left of the median line, and a little above the level of the umbilicus. At this time vomiting commenced at intervals of a few days, and the patient states that the ejected material sometimes had the appearance of coffee-grounds. During the last three months emaciation has been alarmingly rapid. At the time of admission a tumor was found about the junction of the left hypochondriac with the epigastric regions, and two inches above the umbilicus. The tumor could be moved from side to side, and ascended and descended synchronously with the respiratory movements. Although the tumor apparently involved the cardiac portion of the stomach, the clinical symptoms pointed to obstructive disease of the pylorus. Its anatomical location was definitely demonstrated by insufflation. During the inflation the tumor changed its position, and when the stomach was well distended it could be distinctly felt and mapped out by percussion at a point a little below the normal situation of the pylorus, while the large curvature of the stomach could be plainly outlined about three inches below the level of the umbilicus. It was evident that the organ had assumed nearly a vertical position, owing to the long-standing pyloric obstruction and the great dilatation resulting from it. During the preliminary treatment it became evident that the carcinoma had ulcerated, as on several occasions traces of blood were found in the fluid which returned from the stomach. Gastro-enterostomy was performed by the aid of soft decalcified bone-plates, April 10, 1889. The tumor was found to occupy the pyloric region, and had encroached upon the stomach to the extent of several inches. Although the tumor was very large—the size of an adult's fist—it was freely movable and not adherent to any of the surrounding organs; but the lymphatic glands behind it, and in the great omentum, were extensively infiltrated. On account of the extent of the disease the anastomotic opening in the stomach had to be made nearer the cardiac than the pyloric end. The part of intestine selected was the jejunum, about twelve inches below its junction with the duodenum. Superficial sutures all around the borders of the plates. No untoward symptoms after the operation. Stomach-feeding was resumed the fourth day after the operation. The intestinal plate, partially disintegrated, but perfect in outline, was passed per rectum on the tenth day. At the end of the first week the patient developed a sharp appetite, ate and digested well a liberal diet, and gained rapidly in strength, and his appearance had undergone a remarkable change. Action of the bowels normal. External wound healed by primary union throughout. In the evening of the fourteenth day after the operation he complained of nausea and a sense of fulness in the stomach, and became suddenly extremely anæmic, and died within a few hours. Although no autopsy was allowed, the symptoms which preceded the sudden fatal termination left but little doubt that death was caused by profuse hemorrhage into the stomach from the ulcerating carcinoma. This view of the case is supported by the fact that soon after the patient complained of nausea percussion revealed an extensive area of absolute dulness over the region of the stomach.

Case VIII.—Brewer's wife, forty-five years old, German, with no history of malignant disease in her family, and previously in good health, had been the subject of serious disturbances of gastric digestion for about a year. During this time she has lost more than fifty pounds in weight. Vomiting appeared about three months ago, at intervals of several days, and always copious. No blood in the material ejected. I made an examination, February 22, 1890, and advised a gastro-enterostomy, as the symptoms then clearly indicated almost complete closure of the pyloric orifice of the stomach. A well-defined tumor was found near the median line, a little above the umbilicus. The tumor could be displaced readily to either side, but always returned spontaneously to its former location. Irrigation showed that the stomach was greatly dilated, and insufflation demonstrated that the tumor occupied the pyloric extremity. The presence of ulceration was determined by microscopic examination of the contents of the stomach, which revealed numerous blood-corpuscles unchanged by the gastric secretion.

The patient's general health was such at this time that hope could be entertained that she would survive the immediate effects of the operation, and that life might be prolonged by establishing a new outlet from the stomach into the intestine. The operation was declined. The patient returned four weeks later, anxious to submit to any treatment that might offer a chance to check the rapid progress of the disease. Her general

condition had undergone a great change for the worse during this time. Gastric digestion had become nearly suspended, to which were added great loss of strength and progressive marasmus. The tumor had materially increased in size, but remained movable; the stomach had become more dilated, vomiting occurred at longer intervals, and the quantity ejected was correspondingly larger. As the patient's only hope was grounded on the expectation of having an operation performed, I yielded unwillingly to her urgent request, and performed gastro-enterostomy, March 22, 1890. Stomach was washed out after the patient was under the influence of the anæsthetic, as she absolutely refused to have it done before. The tumor presented itself at the middle of the median incision as soon as the abdomen was opened. The serous surface was perforated at different points by the carcinoma, and the affected part of the stomach was found adherent to different organs by neoplastic adhesions. On the posterior surface the tumor was firmly connected with the pancreas. A large portion of the latter organ appeared to be involved by the disease, a circumstance which rendered it very difficult to bring the stomach sufficiently forward into the wound for direct operative treatment. As the disease had extended along the great curvature of the stomach farther than along the upper border, the incision was made nearer the small curvature than usual, in order to make the opening at a safe distance from the carcinoma. The intestine was opened near the junction of the jejunum with the duodenum, and the two visceral wounds were approximated in the usual manner by two large decalcified bone plates and a row of superficial sutures. The intestine was united with the stomach in the position advocated by Rockwitz. The plates used in this case were dry, and had been kept in this condition for some time.

Stimulants and food were administered exclusively by rectal enemata.

The operation was not followed by any symptoms of shock, but the patient made repeated attempts at vomiting before she fully recovered from the effects of the anæsthetic. March 24th, forty hours after the operation, both plates, held together by the four sutures, were ejected during a violent attack of vomiting. Both plates were softened, and at least twice as thick as when they were inserted in the dried state. Although the serous surfaces interposed between the plates were freely scarified before the viscera were approximated and a row of superficial sutures was placed all around the borders of the plates, I was fearful that the adhesions between the stomach and intestine had given way during the violent fit of vomiting which brought up the plates, and that the patient would soon succumb to perforative peritonitis. I was astonished the next day to find the general condition of the patient much improved. She was now allowed liquid food by the stomach, which she retained and digested without any difficulty, and her strength began to improve materially, when, on March 26th, two days after the occurrence of this accident, she was suddenly attacked with typical croupous pneumonia of the lower lobe of the left lung, which proved fatal April 3d, seven days after the initial chill. The external incision healed by primary union, the bowels responded promptly to mild cathartics, and after the ejection of the plates the symptoms of obstruction were entirely relieved. It is well to mention the fact that at the time the operation was made "la grippe" was epidemic in the city and a number of the patients in the hospital were affected by it.

I am convinced that the increased thickness of the plates, owing to the absorption of fluids from the stomach and intestine, caused pressure gangrene of all the tissues interposed between them, and that perforative peritonitis was only prevented by the superficial sutures which secured adhesions between the stomach and intestine around the area of gangrene. This case taught me an important lesson, and since then I have abandoned the use of hygroscopic material for the plates.

Case IX.—Male, aged seventy-one, with a good family history, consulted his family physician August 11, 1889. At this time he was well nourished, body weight 160 pounds, complexion florid; pulse, respiration, and temperature normal. Appetite good, but complains of severe pain in the epigastrium and sensation of weakness in the back. After meals has a feeling of fulness in the stomach and eructations of gas. In the absence of positive physical signs his affection was regarded as a chronic gastric catarrh due to pyloric stenosis from unknown cause.

January 15, 1890, the patient was again examined. He has had for some time persistent vomiting three or four hours after meals. If vomiting did not occur for several days, enormous quantities of a brownish, sour fluid, containing undigested fragments of food, were ejected by repeated efforts. Vomiting, preceded and accompanied by sensation of heat and burning in the pharynx. Sleeps well when not disturbed by vomiting. He had lost a great deal in weight; skin, pale, dry, and scaly; tongue, dry and heavily coated in the middle, edges red and moist. The copious panniculus adiposus had almost completely disappeared. A tumor the size of a child's fist could now be readily detected to the right of the median line and a little below the normal situation of the pylorus. The tumor was movable, and could be displaced to the left of the median line. Irrigation of the stomach revealed enormous dilatation, and insufflation demonstrated that the tumor involved the pyloric extremity. The family were informed of the true nature of the affection, but the patient was told that he had an obstruction at the pyloric orifice which would require an operation in order to obtain the desired relief. The patient was subjected to proper preparatory treatment, after which gastro-enterostomy was performed at the Milwaukee Hospital, January 31, 1890. The disease was found to involve about three inches of the pyloric end of the stomach, and the omental and retro-peritoneal glands were extensively infiltrated. Moist, large, decalcified bone-plates were used. The incision in the stomach was made near the great curvature and about two inches from the margin of the tumor. The upper portion of the small intestine was placed in Rockwitz's position, and after incision was joined to the stomach in the usual manner by approximation-plates and superficial sutures. Although the patient was very anæmic and greatly emaciated, the operation produced no shock or any other untoward symptoms. Stomach-feeding was commenced on the third day, and after the expiration of a week a liberal diet of solid food was allowed. The external incision healed by primary union, and the sutures were removed on the ninth day. The symptoms of obstruction disappeared promptly after the operation, and digestion was fairly well performed. The patient left the hospital, February 13th, in excellent condition, fully confident that the operation had secured for him permanent relief, and that it would add many years to his life. A month later he reported that he had gained eight pounds in weight, and that he could eat all kinds of food without causing pain or discomfort after eating. He conducted his business for eight or nine months, made many distant journeys, and enjoyed life as well as the average man in perfect health. A ventral hernia developed at the site of the external incision, but did not cause much inconvenience. The patient lived for twenty months after the operation, and finally died of marasmus. During the last few weeks digestion was impaired and symptoms of obstruction again appeared, but were not as distressing as before the operation. There can be but little doubt that at this time the carcinoma reached the new pylorus and partially occluded its lumen. It was evident to all who witnessed the operation that, judging from the general condition of the patient and the extent of the disease, life could not have been prolonged for more than a few weeks without surgical intervention.

Case X.—Farmer, aged thirty-seven, was admitted into the Milwaukee Hospital, December 27, 1890. During the last six years he has suffered repeatedly from attacks of indigestion. For the last two months he has had a severe pain in the stomach, which was always aggravated after meals, and was only partially relieved by vomiting. Vomiting has occurred during the same time regularly whenever solid food was taken. As the vomiting came on several hours after eating, pyloric obstruction was suspected some time ago, but considering the age of the patient it was believed that it was of a non-malignant nature. The patient lost twenty pounds in weight in a few weeks. Examination revealed a hard, irregular tumor to the right of the median line, and half-way between the crest of the ilium and the costal arch. The tumor was not affected by the respiratory movements, and on palpation appeared to be firmly fixed by adhesions to surrounding organs, neither was its location changed by inflation. During inflation a tympanitic area could be mapped out on the left side of the tumor, extending far below the level of the umbilicus. Inspection and palpation through the median incision revealed a diffuse carcinoma of the pylorus, which had encroached upon the anterior wall of the stomach to the extent of at least four inches, and had extended to the under-surface of the liver and the pancreas. Posteriorly the tumor had evidently reached the retro-peritoneal tissue, as it formed one common mass with the enlarged retro-peritoneal lymphatic glands and pancreas. In the omentum numerous glands, varying in size from a split pea to an almond, were found. Considering the time since symptoms of obstruction first appeared it was evident that in this case the tumor developed very rapidly, and gave rise to early glandular infection and extension to surrounding organs and tissues by contiguity. Through the incision in the stomach digital exploration showed a soft cancerous mass, occluding almost completely the pyloric orifice. Gastro-enterostomy was made by the aid of large, moist, bone plates, with the intestine in Rockwitz's position. Although unnecessary handling of the abdominal organs was carefully avoided, and the operation was completed in less than half an hour, profound shock set in, which, in spite of active stimulation, proved fatal five hours after operation. At the autopsy, the abdominal incision was found agglutinated, and omentum adherent to the wound. Although the stomach was washed out thoroughly just before the anæsthetic was administered, and was found empty when incised, it contained a large quantity of a viscid fluid which was retained probably on account of complete suspension of muscular contraction after the operation, as the anastomotic opening was patent, and fluid could be forced through it in a large stream. Only a very small stream could be forced through the pylorus, showing that its lumen was almost completely obliterated by the ulcerating carcinoma. Approximation of serous surfaces was so perfect that under considerable pressure no leakage could be produced. Nearly half of the pyloric portion of the stomach was infiltrated. The extension of the disease to surrounding organs, ascertained during the operation, was verified by the autopsy. The result of my observations has been that when young persons are the subject of carcinoma of the stomach, the disease pursues a more rapid course and results early in extension to other organs and diffuse infiltration of the retro-peritoneal and omental lymphatic glands.

Case XI.—German, farmer, aged forty-five, was admitted into Milwaukee Hospital, January 21, 1891. Maternal uncle died of carcinoma of the stomach at the age of fifty; patient has always been in robust health until six months ago when at intervals of several days he began to vomit about midnight. A month later a burning pain appeared in epigastrium, radiating toward the right side, which was always relieved by vomiting. The vomiting became more frequent, and the amount of fluid ejected more copious in the course of time. During the last few weeks the simplest articles of food have remained undigested in the stomach, and could be identified in the large quantities of dark viscid fluid thrown up daily by vomiting. Within a few weeks the patient has lost thirty-five pounds in weight. Lavage of the stomach always afforded temporary relief. Patient presents an anæmic and marked cachectic appearance. No tumor can be felt in the pyloric region, either before, during, or after insufflation. Insufflation, however, reveals enormous dilatation of the stomach. The history of the case and the leading symptoms clearly indicated the existence of pyloric stenosis. The general condition and the rapidly increasing stenosis left but little doubt as to the malignant nature of the obstruction. The patient was exceedingly anxious to avail himself at this stage of the doubtful benefits that might be derived by surgical intervention, and at his urgent request gastro-enterostomy was performed the day after he entered the hospital. Large moist plates were used, and the intestine, at a point about thirty inches below the pylorus was attached to the stomach in Rockwitz's position. No circumscribed tumor was found, but several inches of the pyloric end of the stomach were diffusely infiltrated and the walls much thickened. Diffuse infiltration had also taken place toward the duodenum, even the unaffected portion of the stomach, which was considerably dilated, presented an œdematous appearance; numerous lymphatic glands behind the tumor and in the great omentum, varying in size from a hemp-seed to a large pea. At the close of the operation, which was finished in less than half an hour, symptoms of shock appeared. The patient rallied under the judicious use of stimulants and the external application of dry heat. No untoward symptoms after the patient rallied from the immediate effects of the operation. No vomiting. Bowels moved freely on the second day. On the fourth day stomach-feeding was resumed, and the food administered caused no distress. Sutures were removed on the ninth day, at which time the incision was found healed. The patient appeared to improve for a week, when, in spite of a liberal allowance of easily digestible food, which was retained and digested, his strength gradually failed and he died of simple exhaustion, February 9th, eighteen days after the operation. It is apparent that in this case the operation proved a surgical success, but that it was performed too late to add much to the duration of the patient's life.

Case XII.—Laborer, thirty-five years of age, suffering from advanced carcinoma of the pylorus, came to the Milwaukee Hospital, March 28, 1891, for the purpose of subjecting himself to surgical treatment for pyloric carcinoma. He has always been in good health until about nine months ago, when he began to have a feeling of heaviness and oppression in the stomach a few hours after meals, followed by increasing pain, especially toward evening, which was only partially relieved by vomiting. Vomiting occurred regularly every second or third day. The gastric distress and vomiting gradually increased in intensity and frequency, and he commenced to lose flesh rapidly. At the present time he is unable to retain and digest any solid food, and in consequence of long-continued defective nutrition presents an exceedingly marantic appearance. A round, smooth, movable tumor in the pyloric region was easily detected and recognized as a carcinoma of the pylorus. The short duration of the disease and the great mobility of the tumor made me hopeful that I would be able to make a pylorectomy, and the necessary preparations were made for this operation.

Operation: March 30, 1891. On opening the abdomen the tumor was found free, and limited to organ first affected. Examination of the space behind the tumor revealed numerous enlarged lymphatic glands, a condition which induced me to abandon the intention of removing the carcinomatous pylorus, and to substitute for this operation a gastro-enterostomy. The operation was completed in twenty-five minutes. The upper portion of the small intestine was placed in Rockwitz's position before the anastomosis was made. The patient recovered from the operation without a single untoward

symptom, and after the fourth day, when stomach-feeding was commenced, gastric digestion was performed in a satisfactory manner. The external incision healed by primary intention, and the sutures were removed on the ninth day. The patient left the hospital at the end of the second week, and from subsequent information received I learned that he lived three months in comparative comfort, and finally died of marasmus. The anastomotic opening in this case remained patent, and served as an efficient outlet for the chyme, as little or no food could pass through the obstructed carcinomatous pylorus.

Case XIII.—Male, aged forty four, German, carpenter by occupation; was sent to the Surgical Clinic of Rush Medical College for diagnosis and opinion concerning a chronic affection of the stomach six weeks prior to the operation. He stated that for a number of years he had been the subject of frequent attacks of indigestion and that he had been unable to eat heavy articles of food without bringing on one of these attacks. During the last year the gastric disturbances have come on at shorter intervals and with greater intensity. Three months ago he first commenced vomiting daily a few hours after the principal meal, and this symptom has recurred at regular intervals ever since. During this time he has lost a great deal of flesh and strength, and even at the time of the first examination he presented a decidedly cachectic appearance. In the region normally occupied by the pylorus, but a little lower down, a hard nodular tumor can be distinctly felt. Irrigation and insufflation of the stomach prove that the organ is greatly distended. During the insufflation the large curvature of the stomach can be outlined distinctly about four inches below the umbilicus; at the same time the tumor is forced a little to the right without changing its relative position to the anterior abdominal wall. The diagnosis made at that time was carcinoma of the pylorus, causing obstruction and dilatation of the stomach. As at this time gastric digestion was nearly suspended, and the patient had already become greatly debilitated from this cause, a gastro-enterostomy was advised.

Nothing was seen or heard of from the patient until five weeks later, when he again made his appearance in the clinic and begged to have the operation performed. In the meantime he had become emaciated to a skeleton. Eyes were sunken in their sockets, cornea lustreless, skin wrinkled and of a dark bronze hue, and ankles œdematous. The tumor had increased in size and the dilatation of the stomach had reached such an extent that the organ was unable to expel its contents by vomiting. The large curvature nearly reached to the pubes. A large quantity of a dark viscid fluid was evacuated from the stomach through an elastic siphon-tube, which afforded temporary relief. The rapid extension of the local disease and the general critical condition of the patient induced me to advise against an operation, as I was almost convinced that the patient could not survive the immediate effects of the anæsthetic and the shock produced by an operation even of very short duration. The patient would not listen to my objections, and insisted that the operation should be performed, regardless of consequences. I finally yielded to his earnest pleadings, and operated on him before the class, August 21, 1891. For two days prior to the operation the stomach was washed out twice daily, and during this time the patient's strength was supported by rectal alimentation consisting of injections of peptonized milk, beef-tea, and eggs prepared with sodic chloride. A subcutaneous injection of one-sixtieth of a grain of atropia and a rectal enema of two ounces of whiskey in a teacupful of warm water were given in order to guard against shock during and after the operation. Owing to the feebleness of the heart's action ether was used as an anæsthetic in preference to chloroform. The carcinoma extended from the pylorus to the junction of the outer with the middle third of the stomach. The tumor was firmly attached by neoplastic adhesions to the surrounding organs. Omental and retro-peritoneal glands extensively infiltrated. The incision in the stomach was made near the centre of the organ, and with it was united a similar incision of the small intestine near the junction of the jejunum with the duodenum, the intestine being placed in Rockwitz's position before the approximation with large decalcified bone-plates was made. Scarification of the serous surfaces and suturing along the outer border of the plates were done in the same manner as in the preceding cases. The operation occupied less than half an hour, yet near its completion the pulse became very rapid and feeble, the extremities cold, and the pupils widely dilated. In spite of active stimulation by subcutaneous and rectal injections, and the external application of dry heat, the patient did not react from the immediate effects of the operation and died eight hours later.

Table of Thirteen Gastro-enterostomies for Malignant Pyloric Obstructions.

Case.	Sex.	Age.	Duration of Disease.	Result.	Remarks.
1	Male.	67	1 year.	Recovered.	Died five days after operatioo, of exhaustion.
2	"	47	18 months.	"	Improved for several weeks; died of marasmus three months after operation.
3	"	35	6 "	Died.	Immediate cause of death, intestinal obstruction at site of operation; death three weeks after operation.
4	"	43	1 year.	Recovered.	Improved for several weeks; died of marasmus four months after operation.
5	"	38	6 months.	Died.	Immediate cause of death, perforative peritonitis.
6	"	69	1 year.	"	Cause of death, shock, two hours after operation.
7	"	32	9 months.	Recovered.	Death from hemorrhage into the stomach, from ulcerating carcinoma, nine days after operation.
8	Female.	45	1 year.	"	Died twelve days after operation, from croupous pneumonia.
9	Male.	71	16 months.	"	Improved for several months, and died of marasmus twenty months after operation.
10	"	37	4 "	Died.	Cause of death, shock, five hours after operation.
11	"	45	6 "	Recovered.	Died eighteen days after operation; immediate cause of death, marasmus.
12	"	35	9 "	"	Improved for several weeks, and died of marasmus three months after operation.
13	"	44	1 year.	Died.	Died eight hours after operation; immediate cause of death, shock.

Remarks.—Adding the 2 pyloro-plastic operations to the 13 gastro-enterostomies we have 15 operations on the stomach for malignant and non-malignant stenosis of the pylorus, of which number 10 recovered and 5 died, a mortality of 33.3 per cent. Of the 13 operations for carcinomatous pyloric obstruction on as many patients 12 were males and 1 female. The youngest patient was thirty two years of age, the oldest seventy-one; average age, forty-six years and ten months. The duration of the disease could only be ascertained approximately, eighteen months being the longest and four months the shortest period intervening between the first manifestation of symptoms and the time of operation; average duration, ten months and ten days. In most of the cases vague symptoms of gastric derangement preceded the actual development of symptoms pointing to pyloric obstruction for several years, months, or weeks. In all of the cases the existence of pyloric obstruction at the time of operation was evident from the complexus of symptoms present at the time, the results of physical examination, and, in most instances, verified by digital exploration of the pylorus during the operation. In only one case did I fail in detecting enlarged lymphatic glands in the vicinity of the carcinoma, and that was the first case reported, in which I found an annular malignant stricture without involvement of the serous coat and adjacent lymphatic glands. This would have been a proper case for pylorectomy had the patient's general condition warranted such an operation. In all of the remaining cases the carcinoma was

more extensive, and the lymphatic glands in its vicinity infiltrated, and in many of the cases the growth was connected with one or more of the surrounding organs by neoplastic adhesions. In all of these cases the local conditions were of such a nature that a radical operation by pylorectomy was out of the question, irrespective of the general condition of the patients. Analysis of the immediate and remote results of the thirteen cases of gastro-enterostomy shows the following: Eight of the patients survived the immediate effects of the operation and five died. Among the recoveries are included all cases in which the immediate cause of death could not be attributed to the operation. In Case I. death occurred five days after operation, from exhaustion. Nothing occurred that would tend to show that the operation shortened life. The patient was extremely anæmic and emaciated at the time of operation, but he rallied from its immediate effects promptly; the symptoms of obstruction were relieved but he gradually sank, and died five days later from simple exhaustion, due to the disease and its secondary consequences, and not to the operation. In two other cases reported as recoveries death occurred in one, twelve days after operation, from croupous pneumonia, in the other, on the ninth day, from hemorrhage into the stomach from the ulcerating carcinoma; in both instances the external incision had healed, the symptoms of obstruction were removed, and gastric digestion was partially restored. The remaining five cases that recovered lived, respectively, one, eighteen days; two, three months; one, four months; and one, twenty months after the operation, and finally died of marasmus. The most remarkable of these was Case IX., the oldest patient on the list, who had been suffering from pyloric carcinoma for sixteen months, and who at the time of operation certainly could not have lived for more than a few weeks without surgical intervention. This patient recovered without a single untoward symptom, lost the cachectic appearance, gained a number of pounds in weight, resumed and conducted his business for eight months, and died of marasmus twenty months after operation. Billroth makes the statement that in none of his cases of gastro-enterostomy for malignant pyloric obstruction was life prolonged for more than a year after the operation. Two of my patients lived three, and one four months after operation, and in none of them did symptoms of pyloric obstruction appear after the operation. In Case III. an autopsy was made. The dilatation of the stomach had disappeared, the anastomotic opening was large enough to admit the tips of two fingers, and was lined throughout by mucous membrane. In the five fatal cases death occurred in from two hours to three weeks after operation. In three of these the patients succumbed to the immediate effects of the operation in two, five, and eight hours. One died of perforative peritonitis on the fifth day, and in one death was caused by intestinal obstruction three weeks after operation. In the last case the intestine was attached to the stomach at a point eight feet below the pylorus. At a point nearly in the centre of the opening in the bowel a sharp flexion was found at the autopsy, and in consequence of this flexion the mesenteric portion of the bowel formed a spur, which directed the contents of the stomach into the portion of bowel on the proximal side of the anastomotic opening. In view of the extent of the local disease, the gravity of the secondary lesions due to long-standing pyloric obstruction, and the serious impairment of the general health present in all the cases, the immediate and remote results as given above must be regarded as satisfactory.

The important lesson to be drawn from these cases is not to postpone operative treatment for pyloric obstruction until the patient's strength is so much reduced that death would be likely to ensue from the immediate effects of an operation of even very short duration. In a number of the cases reported above, an operation was advised in time, but was refused until the patient had become convinced by sad experience that it offered the only chance of relief; but in the meantime the local and general conditions had become so much aggravated that the prospects of success were reduced to a minimum. More than one of the patients, when he had reached this desperate condition, threatened to put an end to his sufferings by suicide in case an operation was refused, and this determination more than once turned the scales when I hesitated to carry into effect their request. Patients suffering from pyloric stenosis must be informed in time of the inefficacy of all methods of treatment short of removal or rendering harmless the obstruction by operative treatment. The results of gastro-enterostomy for malignant stenosis of the pylorus will improve and become more satisfactory as soon as the profession will sanction early surgical interference and patients can be made to submit to it as soon as a positive diagnosis can be made.

In conclusion I beg to submit the following propositions for your further consideration and discussion:

1. Pyloroplasty, as devised by Heineke-Mikulicz, is the safest and most efficient operation for cicatricial stenosis of the pylorus.

2. Pylorectomy in the treatment of carcinoma of the pylorus is a justifiable procedure when the disease is limited to the organ primarily effected and the patient's general condition furnishes no contra-indication.

3. Gastro-enterostomy by the aid of large, moist, perforated plates of decalcified bone should be resorted to in the treatment of malignant stenosis of the pylorus as soon as a positive diagnosis can be made, and a radical operation is contra-indicated by local or general conditions of the patient.

532 Dearborn Avenue.

INJURIES CAUSED BY THE CONCUSSION PRODUCED BY EXPLOSION OF TORPEDOES BENEATH IRON CLAD AND OTHER VESSELS OF WAR IN MOBILE BAY, 1865.

By J. RUFUS TRYON, A.M., M.D.,
SURGEON, UNITED STATES NAVY.

During my professional career of nearly thirty years, as a medical officer in the United States Navy, nothing has been more interesting than a series of cases, disabled by complicated injuries, occasioned by the concussion caused by the explosion of torpedoes beneath iron-clad and other vessels of war. While the effects of concussion produced by ordinary causes are familiar to every one in general practice, there is very little in surgical history relating to the many forms of injury that may accompany shock caused by the force referred to. Since the War of the Rebellion the torpedo, as a weapon of warfare in naval engagements, has been so improved in construction and management that its use is indispensable both for attack and defence, and in the naval battles of the future most medical officers of the navy will be brought in contact with the class of injuries under consideration. For this reason I have thought it might be of professional interest to submit the few authentic notes I have in my possession on the subject. Every case cited came under my immediate charge during the war, and the history of each one embraces facts taken from my note-book at that time, official records on file in the Bureau of Medicine and Surgery, Navy Department, "Surgical History of the Rebellion," and Pension Office, Washington, D. C.

In the second attack on Mobile, during the months of March and April, 1865, there were twenty killed and thirty-two wounded by concussion produced by the explosion of torpedoes beneath the following vessels:

Vessel.	Rate.	Class.	Killed.	Wounded.	Remarks.
Osage	4th	Ironclad	5	11	2 severely wounded.
Sciota	4th	Gunboat	6	6	1 severely wounded.
Rodolph	4th	Timclad	4	11	4 severely wounded.
Ida	4th	Screw tug	3	2	
Althea	4th	Screw tug	2	2	2 severely wounded.

Among the wounded temporarily cared for on board the Hospital-ship in the bay of Mobile, and afterward transferred to the United States Hospital, Pensacola, Fla., there were four cases of dislocation of the tibia backward, one complicated with a compound comminuted fracture of both bones of same leg; one case of compound comminuted fracture of both bones of right leg; one case of compound comminuted fracture of left forearm; one case of fracture of dorsal vertebra; one case of fracture of fibula; one of concussio cerebri, and two of subluxation—one of ankle and one of wrist.

All of these injuries were complicated with severe contusions, and the patients, in the first instance, labored under all the serious symptoms consequent upon severe shock.

Every one conversant with the anatomy of the knee-joint and bony structure of the body will understand the strength and extent of a force that must be exerted, and unexpectedly applied, to produce a series of injuries so different from those usually caused on shipboard during the ordinary naval engagement, or sustained by other causes. To give an example of the force in question, I cite the case related to me by the Fleet Surgeon on board the Rebel ram Tennessee, during her fight, at close quarters, in the first engagement in Mobile Bay, August 4, 1864. A man belonging to one of the gun's crew on board rested for a moment against the inclined side of the iron-clad, near the gun where he was stationed, when a shot at short range struck the vessel's side near the place where he was partially bracing himself, producing a concussion so great in effect that in an instant he was literally "blown to atoms," and the contused and mangled portions of his body scattered in every direction over the deck.

Case I. *Dislocation of Left Tibia Backward.*— William H——, ordinary seaman, aged twenty-seven, native of Pennsylvania, constitution strong, on March 29, 1865, on board the United States Steamship Osage, received the above injury, by concussion produced by explosion of a torpedo beneath that vessel. The injury was accompanied with severe contusions both of right and left thigh, and left leg. When patient was admitted to Naval Hospital, Pensacola, Fla., two days after injury, the dislocation had been reduced and temporary dressings applied. Treatment in hospital consisted in moulding pasteboard splints to limb, keeping extremities at perfect rest on a double inclined plane, and application of water-dressings. With all this care, however, suppuration of tissues of thigh and leg followed, necessitating deep incisions into the parts for the free escape of pus. Patient became emaciated to a great degree by the profuse discharge and irritative fever, and was confined to bed in the position described till July 1, 1865. July 8th, H—— was sent North by Medical Survey, and remained under treatment at Naval Hospital, New York, till November 25, 1865, when he was discharged from the service disabled, but general health much improved.

Case II. *Dislocation of Left Tibia, with Compound Comminuted Fracture of Tibia and Fibula near Ankle-joint of same Leg.*—E. R——, a landsman (colored), aged twenty-four, while attached to the United States Steamship Rodolph, was wounded in the left leg by concussion produced by the explosion of a torpedo beneath that vessel, in Mobile Bay, April 1, 1865. The injury involved a dislocation of the tibia at the knee, and a compound comminuted fracture of the fibula and tibia near the ankle of the same leg. The fracture was impacted as well as comminuted. When he was admitted to the Naval Hospital at Pensacola, three days afterward, the dislocation had been reduced; but on examination (the patient being under the influence of chloroform) both the tibia and fibula were found to be severely injured near the ankle, the bones protruding from the wound, and large and small fragments being easily felt by introducing the finger. It was then deemed useless to attempt to save the limb, and I amputated the leg about four inches above the injury. The dislocated bone was kept in position by pasteboard splints, and the greatest care was used in dressing the stump. The case progressed favorably until April 22d, when the patient complained of headache and nausea, followed in a short time by a severe chill and high fever. Pyæmia being apprehended, the stump, though nearly healed at the time, was carefully examined, and fluctuation was detected at the under portion near the cicatrix. After the escape of pus by free incision into this part, the patient, who was a man of strong constitution, over six feet high and stout in proportion, improved rapidly under the administration of quinine, and was soon able to be transferred to New York, where he entered the Naval Hospital on June 15th. He was discharged from service November 24, 1865, with a good stump, being able to walk easily and well on an artificial limb, and suffering no weakness of the knee consequent upon the dislocation. I contributed the notes in this case to the "Surgical History of the War of the Rebellion," and also forwarded the amputated bones of the leg, which constitute Specimen 5,662 of the Surgical Section of the Museum, and exhibit the seat of the injury, including a longitudinal fissure of the tibia about three inches in length. The man is a pensioner, and was paid September 4, 1880. He reported the stump as continuing in "good and healthy condition." It is an interesting fact that by Government record I have been able to trace this case for fifteen years after receipt of injury.

Case III. *Dislocation of Right Tibia Backward.*—E. W——, first-class boy (negro), aged seventeen, constitution strong, received the above injury, April 1, 1865, on board United States Steamship Rodolph, by concussion produced by explosion of torpedo beneath said vessel. The dislocation was reduced soon after receipt of injury. On admission to hospital considerable tumefaction existed about the knee and leg, accompanied with severe pain. Treatment: Application of the pasteboard splint, rest, and cold-water dressings. July 8, 1865, had sufficiently improved to be sent North. Patient remained under treatment at the Naval Hospital, New York, until September 18, 1865, when he deserted—condition at the time, disabled.

Case IV. *Dislocation of Left Tibia Backward.*—S. C——, a fireman, attached to the United States Steamship Rodolph, aged twenty-one, and of a strong constitution, sustained a dislocation of the left tibia, backward, during the action in Mobile Bay, April 1, 1865. Injury by concussion. He was admitted to the Naval Hospital, Pensacola, Fla., three days afterward. The luxation was reduced, but there was considerable swelling of the limb, accompanied by inflammation. The treatment consisted in moulding pasteboard splints to the limb, in keeping the extremities at perfect rest on a double inclined plane, and in applying water-dressings. Ten weeks after his admission the patient was transferred to Naval Hospital, New York, where he was discharged for disability, June 30, 1865, with probabilities of regaining full use of the limb. In sending the notes of this case for the "Surgical History of the Rebellion" I supplemented the history with the following remarks: "From the severity of this and other cases, I think the dislocation of the tibia in each must have been complete. Considerable deformity about the knee existed for months after the injuries, and the joints in most of them were impaired in some degree by the inflammation, adhesion, etc., which invariably follows." This case, five years after injury, was seen by Examining Surgeon L. Jemison, of Bordentown, N. J., and he reported: "The bones of the leg now stand a little back from their normal position, and the joint seems movable upon the cartilages. He complains when standing any length of time upon his feet, and falls from a slight touch to the limb," etc. The Philadelphia Examining Board, in October, 1873, certified to "grating in the knee-joint when moved; ligaments relaxed, and knee falls back, unless supported, when his weight is borne upon it," etc. At subsequent dates the same Board reported that "the patella projects forward, and the in-

ternal tuberosity projects inward." Also, that there is decided crepitus, and that deformity is caused by dislocation of the internal semilunar cartilage of the knee. The pensioner was paid June 4, 1881.

Case V. *Compound Comminuted Fracture of Tibia and Fibula, Lower Third, and of Tarsal and Metatarsal Bones of Right Extremity—Wound in Sole of Foot Communicating with Fracture.*—William G. B——, boatswain's mate, aged thirty-nine, constitution strong, received the above injury, March 29, 1865, on board the United States Steamship Osage, by concussion caused by explosion of torpedo beneath that vessel. The patient came under my care April 1, 1865, and was immediately placed under the influence of chloroform and the limb carefully examined. I never saw such complete destruction of bone, the fractured ends of tibia and fibula were driven down into the tissues of the foot, the tarsal and metatarsal bones separated and fractured, and every fragment appeared to be embedded in one mass covered only by the skin; the wound in plantar surface was small externally, and an ordinary probe directed upward could be passed into it nearly its whole length. Amputation was performed at once at middle third, circular operation. June 15, 1865, patient was sent North, and remained under treatment at Naval Hospital, New York, until August 5, 1865, when he was furnished with an artificial limb and discharged from the service. When amputation followed these injuries the "circular operation" was modified by a longitudinal incision from two to three inches in length through integument, in the direction of spine of tibia, to enable the flap to be easily turned backward for the second incision. This modification was serviceable and judicious in these cases, on account of the distention and engorgement of the tissues, and greatly facilitated the operation. The unhealthy condition of the stumps, and the tendency to sloughing following amputations for injuries resulting from causes described, must be attributable partly to the extravasation of blood in the severely contused tissues.

Case VI. *Compound Comminuted Fracture of Left Ulna.*—William S——, coal-heaver, aged twenty-six, negro, received the above injury by concussion, April 1, 1865, on board the United States Steamship Rodolph, patient at the time standing with his left hand resting on a gun-carriage. After admission to hospital, April 4, 1865, he was placed under the influence of chloroform, and the arm carefully examined. The wound was large, contused, and lacerated, the ulna severely comminuted at middle and lower third, detached fragments of bone embedded in the muscular tissues. As the artery and nerve remained unimpaired, resection of the bone was performed, about six inches in all being removed. During the after treatment the same tendency to sloughing was noticed as in the previous cases, with the formation of abscesses in palm of hand and side of arm. June 15, 1865, the patient was sent North, with wound healed and gradually obtaining use of hand. He remained at Naval Hospital, New York, until July, 1865, when he was discharged to duty, with good use of arm and hand.

Case VII. *Fracture of the Twelfth Dorsal Vertebra.*—W. P——, sailmaker's mate, aged thirty-four, of a weak constitution, received the above injury by concussion, April 14, 1865, on board the United States Steamship Sciota, Mobile Bay. The patient, when admitted to hospital at Pensacola, Fla., April 18, 1865, suffered excruciating pain on the slightest movement of the body; there was paralysis of lower extremities and of bladder, anxious countenance, feeble pulse, and evidences of exhaustion, followed in a short time by still more serious symptoms; large bed sores quickly developed by the accompanying contusions of back, thigh, and legs; involuntary discharges of fecal matter, etc. Patient died twenty one days after receipt of injury.

Treatment.—Perfect rest, with head low, on comfortable bed, paralyzed extremities protected, and cleanliness of body; urine regularly removed with catheter; tonics, stimulants, etc., freely administered. The patient's mind continued clear until the day before death.

Autopsy revealed a complete impacted fracture of twelfth dorsal vertebra, and a fracture of corresponding ribs of right side, near vertebral articulation. Cord in position, but evidences of laceration of its coverings, and cavity filled with pus; spleen pulpy; bladder inflamed. The specimen of bone in this case was forwarded to the Army Medical Museum, Washington, D. C. No. of specimen, 2,447.

Case VIII. *Fracture of Fibula, Lower Third Right Leg.*—Michael M——, seaman, aged thirty, received above injury by concussion, on board United States Steamship Osage, March 29, 1865. Plaster-of-Paris dressings applied to injured limb soon after admission to hospital, April 1, 1865. Dressings removed May 15, 1865, and patient discharged to duty May 24th. No deformity.

Case IX. *Concussio Cerebri.*—Nicholas H——, ordinary seaman, aged twenty-one, constitution strong; shock occurred on board United States steamship Osage, March 29, 1865, by explosion of torpedo beneath that vessel.

On admission to hospital, April 1, 1865, patient had every symptom of compression, and was in a comatose condition. Death occurred the following day.

Autopsy revealed that the compression following concussion was caused by extravasation of blood in the substance of the brain. Clot larger than a walnut found in anterior portion of right cerebral hemisphere.

Cases X. and XI.—These cases of subluxation, one of ankle and one of wrist, remained under treatment one month, when they had sufficiently recovered to be returned to duty.

In reviewing what has been written of injuries produced by concussion, it must be conceded that the prognosis in all such cases is extremely unfavorable. Where death is not instantaneous, the patient suffers temporary concussion of the brain, together with serious contusions, accompanied, in most cases, with dislocation or fracture, and serious wounds of tissue. If the brain-shock is severe, compression follows and death ensues, as in the case of H—— (Case IX.), already noted. Those otherwise disabled suffer long confinement in hospital, and are finally discharged with loss of limb or diseased joints. It may be argued that injuries of this class could only occur on light-draft vessels of war, and men on board larger ships, with the same force applied, would only suffer temporary shock. But it must be remembered that only light-draft vessels can be used in shallow harbors, and with the torpedo of to-day there would probably be complete destruction of both crew and vessel, while the crews of our larger and more modern ships would be liable to every variety of disability, only in a greater degree, that has been shown to occur on the small vessels of the navy during the War of the Rebellion. Histories of late wars show the dread of explosions of the modern torpedo beneath vessels of large tonnage and heavily plated ironclads, knowing such a catastrophe would not only result in destruction of the ship, but be followed also by great loss of life.

During the Turco Russian War every precaution was taken to prevent the action of this great destroying force, and all exposed vessels in the Black Sea were in every instance surrounded by torpedo-nettings, and constant watchfulness was observed, both night and day, to insure safety.

Everyone is familiar with the destruction of the Albemarle by the successful use of the torpedo. It is safe to conclude, in spite of the great advancement made in the construction of war vessels of the present day, and their gradual introduction by our Government into the navy of the United States, that they will all have to combat, in our next war, with a torpedo force that has been developed in power commensurate with the increased strength of the modern ironclad and battle-ship, and the destruction to vessels of that class, and casualties on board when the force is successfully applied, will undoubtedly be greater than during our last war. Medical officers of the navy, therefore, in time of war can be prepared to

encounter a series of injuries by concussion exceeding in number and quite as formidable as those that have been reported.

The appended table, giving list of vessels destroyed by torpedo boats and torpedoes during the war 1861 to 1865, with number of lives lost, is of interest:

Name of Vessel.	Date of Engagement.	Number Killed.	Number Drowned.
Baron de Kalb	July, 1863	None	None.
Cairo	December 12, 1862.	None	None.
Housatonic	February 17, 1864..	.....	5
Baxley	December 10, 1864.	2	.....
Commodore Jones	May 6, 1864	1	2
Harvest Moon	March 1, 1865	1	.....
Patapsco	January 15, 1865...	.....	61
Tecumseh	August 5, 1864.....	.....	91
Althea	March 12, 1865....	2	None.
Ida	April 13, 1865.....	3	.....
Otsego	December 9, 1864..	1	.....
Sciota	April 14, 1865.....	6	.....
Milwaukee	March 27, 1865	None	None.
Osage	March 29, 1865	5	.....
Rodolph	April 1, 1865.....	4	.....
Total		25	159

I might add, as a recent illustration of the torpedo force, that during the engagements between the naval forces of Chili and those of the insurgents, that the large ironclad Blanco Encalada, and the powerful monitor Huascar, were both sunk by the explosion of torpedoes. The Huascar was 180 feet long, 35 feet beam, and 1,100 tons burden, with an average speed of thirteen knots. She was built by the Messrs Lloyd, on the Clyde, and when cleared for action her deck was but four feet above the water.

A COMBINED LAPAROTOMY AND GYNECOLOGICAL OPERATING-TABLE.

By GEORGE M. EDEBOHLS, M.D.,

GYNECOLOGIST TO ST. FRANCIS HOSPITAL, NEW YORK.

An operating-table claiming to meet all the requirements of modern abdominal and gynecological surgery should combine the following features:

1. Its construction should be simple, so as to permit of ready and thorough cleansing of all the parts, and, if need be, of sterilization of the entire table.

2. It should allow of irrigation *ad libitum* without wetting the clothing of patient, operator, or assistants.

3. It must provide for elevation of the pelvis—the so-called Trendelenburg posture—in the performance of abdominal section.

4. It should permit of ready turning, so as to allow the axis of light to fall as needed upon different portions of the field of operation, a point of especial importance in intra-pelvic surgery.

5. It should afford facilities for the ready performance upon the same patient, at the same sitting, of combined operations; and by this term I mean more particularly the combination of abdominal section with operations upon the uterus, vagina, and perineum.

6. It should enable us to dispense as far as possible with superfluous assistance and accessory apparatus, thus simplifying operative procedure.

With these requirements in view, the operating-table presently to be described was designed and constructed. It is a modification of the writer's laparotomy table presented to the Gynecological Section of the Tenth International Medical Congress. The modifications were chiefly for the purpose of adapting it to the performance of operations upon the uterus, vagina, perineum, etc., and to the readier employment of the Trendelenburg posture. As the table now stands, I have had it in continuous use since February 6, 1891, and for the purposes of my special work it leaves very little or nothing to be desired. In addition to the purposes for which it was especially designed, it meets most of the requirements of general surgery, and could be readily modified to meet them all. Such a modification has, I believe, already been attempted by one of our leading New York surgeons.

Polished plate glass and galvanized metal are the only materials which enter into the construction of the table. Galvanized iron and brass will not rust, and are not affected by even strong solutions of sublimate. A piece of either of them allowed to remain over night in a 1 to 500 bichloride solution comes out bright and untarnished. All parts of the table can thus be freely scrubbed or immersed in a bichloride solution, and the entire table can be subjected, without injury, to prolonged steaming, boiling, or to a dry heat of 100° C. and over. By this means the table, howmuchsoever fouled, can be sterilized and rendered aseptic.

The frame *A* of the table-top is cast in one piece of metal, with all corners and angles well rounded for purposes of ready cleansing. After uniting frame and legs all joints are filled, the metal surfaces smoothed, and the table finally galvanized as a whole. This secures the filling of any crevices and makes a practically unbroken surface continuous over the entire framework of the table.

The table-top (Fig. 1) measures 20 × 49 inches over all, and consists of two plates of polished French glass,

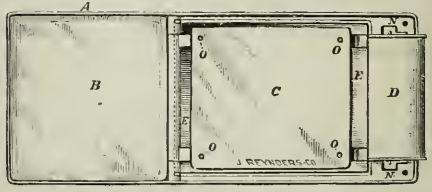

FIG. 1.—Top of Table. *A*, metal frame; *B*, polished glass plate for head and shoulders; *C*, ditto, for body; *D*, metal surface; *E*, trough; *N*, holes for foot-supports.

B, *C*, one-half inch thick, with rounded and polished edges and corners, and of a smooth metal surface, *D*. The glass plate *B*, 19½ inches square, supports the head and shoulders of the patient. It is removable from the frame for purposes of cleansing. The greater part of the trunk and part of the thighs of the patient rest on plate *C*, which is 19 × 16½ inches in size, and also removable. The metal surface *D* is 15 inches wide, 7 inches long in its horizontal, and 12 inches long in its vertical portion. The horizontal part supports the lower portion of the thighs, while the legs are flexed so as to bring the calves against the vertical prolongation. Two metal bars, cast in one piece with *D*, pass under *C*, supporting the latter, and are hinged upon a pinion passing across the table between the two glass plates. This pinion can be withdrawn, allowing of removal of all the parts for easy cleansing. Two projecting pins pass from each of the two metal bars through corresponding perforations, *O*, in the glass plate *C*, to keep the latter from sliding when *D* is elevated. The glass plate *C* is separated by intervals or spaces, 1¼ inch wide, from *B* above, *D* below, and the frame of the table on either side. All fluids used in irrigation pass over the edges of *C* into a trough, *E*, swung beneath, which conducts them into a receiving vessel, *F*, standing on the glass shelf *G* (Fig. 2). This permits of free washing of the abdominal walls before, or of flushing of the abdominal cavity during, an operation, without wetting the clothing of patient or operator.

When *C* and *D*, with the patient in position, are elevated—the Trendelenburg posture (Fig. 3)—the ratchets of *H*, catching upon the bar *J*, allow of any desired height being maintained, or of an almost instantaneous change in the degree of elevation being effected at any time.

The table stands thirty-two inches in height, and is mounted upon casters to permit of ready turning during an operation. The height may of course be varied to suit the height or fancy of the operator.

The table, as already stated, is designed for the per-

formance of both laparotomies and the various operations upon perineum, vagina, and uterus. It has also served me well in the performance of Kraske's operation, the patient being placed upon the abdomen with the lower extremities pendant over the lower edge of the table, which is then elevated until a comfortable height for the operator is attained. The head and lower extremities being thus lower than the buttocks, an artificial ischæmia of the field of operation is produced and the hemorrhage greatly lessened.

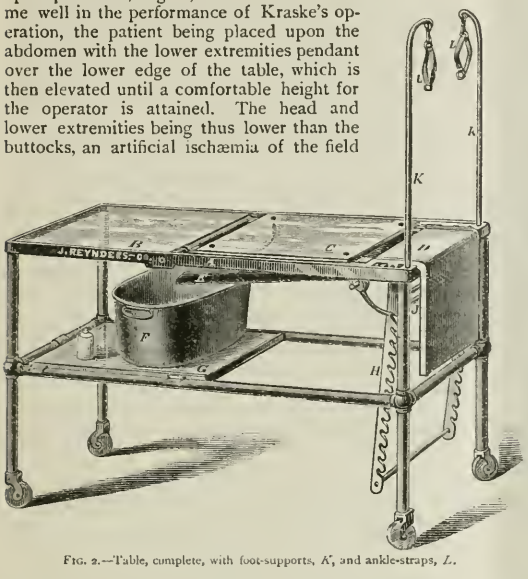

Fig. 2.—Table, complete, with foot-supports, *K*, and ankle-straps, *L*.

The use of the table for operations upon perineum, vagina, and uterus is depicted in Fig. 4. The patient, in the dorsal position, is brought to the lower edge of the table. The buttocks are supported upon *D*, while the ankles are encircled by the foot-straps *L*, and the feet held suspended two feet above the level of the table by the removable uprights *K*. (See also Fig. 2.) This method of securing flexion of the thighs is preferable to any other with which I am familiar. It does away with the necessity of leg-crutches or Beinhalter, with the straps encircling and constricting the neck and shoulder of the patient, and keeps the feet well out of the operator's way. The uprights also prevent the assistants from leaning upon the legs of the patient during operation, and the resultant subsequent complaints of the patient. The clothing is tucked up on to plate *C*, and the freest irrigation of the field of operation can be employed without wetting the patient.

The metal plate *D* takes the place of and renders superfluous the ordinary rubber perineal pad, and conducts all irrigating fluids into the basin *M*. This, to me individually, is a matter of considerable importance, since I have for some years past entirely discarded the use of sponges in operations upon the uterus, vagina, and perineum, and use in their stead constant irrigation during the operation, with sterilized water or weak antiseptic solutions. The ability to raise plate *D*, and with it the buttocks of the patient, to any height, is a convenience appreciated by the operator.

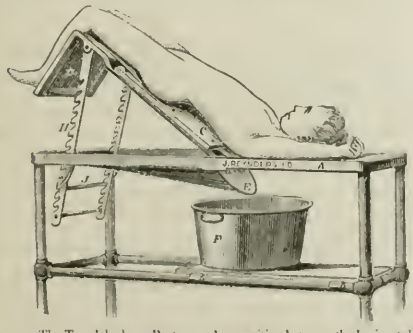

Fig. 3.—The Trendelenburg Posture. Any position between the horizontal and an inclination of 45° may be obtained on the table.

Every laparotomy table, to be complete, must be provided with facilities for the Trendelenburg posture (Fig. 3). The cut represents a patient of average size upon the table. Should the patient be particularly tall, a rubber covered cushion placed beneath the calves will bring her into proper position. This posture has become well-nigh indispensable in pelvic surgery, and after a constant use of it extending over a period of more than two years, I can but reiterate what I said at a meeting of the New York Obstetrical Society, February 17, 1891 :[1]

"Incidentally I would mention that the four operations at which the above specimens were obtained were all performed with the aid of the so-called Trendelenburg position—*i.e.*, with the pelvis elevated, the body resting upon an inclined plane, forming, with the horizontal plane of the table, various angles up to one of 45°. I desire particularly to call the attention of abdominal surgeons to this position, the manifold and obvious advantages of which, in the practice of pelvic surgery, are not yet sufficiently appreciated in this country. The obliging manner in which the intestines gravitate toward the diaphragm out of the operator's way; the increased facility with which the pelvic organs are rendered accessible to sight, touch, and manipulation; the ability to demonstrate these operations to spectators almost as well as those performed in other regions of the body, constitute a revelation when first brought to our notice. I have made use of the position in every one of the laparotomies performed by me within the past eighteen months, and have recently completely reconstructed my operating-table to meet all its requirements. Roughly stated, it reduces by about fifty per cent. the technical difficulties of intra-pelvic surgery, and the wonder to me is now how I ever managed to get along without it. I am sure that I have, by its use, satisfactorily completed more than one operation which formerly I should either have abandoned or performed but imperfectly."

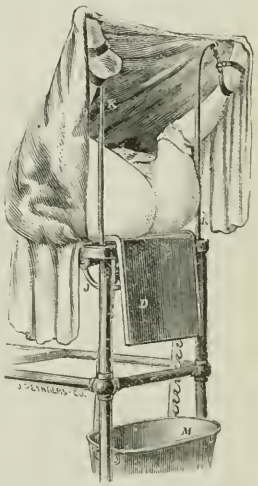

Fig. 4.—The Lithotomy Position, for Examination and for Operations upon Perineum, Vagina, and Uterus. *D*, carrying the buttocks of patient, can be raised to any convenient height.

When laparotomy is to be performed the patient is placed upon the table and anæsthetized. Anæsthesia may be induced in an anteroom, and the table, with the patient upon it, be rolled into the operating-room when unconsciousness has been established. The clothing of the patient is next tucked up on *B* and down upon *D* when the abdomen may be thoroughly scrubbed with soap and water, followed by bichloride solution, ether, etc., all fluids running off glass plate *C* without wetting the patient's clothing. With the exercise of a little care the patient may be returned to bed as dry as she came to operation. This preliminary disinfection, as well as any

[1] American Journal of Obstetrics, May, 1891, p. 597.

subsequent irrigation of the abdominal cavity, is performed with the patient in the horizontal position. When everything is ready for the beginning of operation the pelvis is elevated by an assistant, who can, as often as desired or necessary during the operation, almost instantly lower the patient to the horizontal, or elevate the pelvis to any angle up to 45°. A greater elevation than this I have never found necessary or convenient. The operator may take his position either to the right or left of his patient. I prefer to stand on the right side.

The requirements of modern gynecology often call for the performance of several operations upon a patient at one sitting. Thus, in a woman suffering from laceration of the cervix and of the perineum, it would hardly be excusable at the present day to perform trachelorrhaphy or an amputation of the cervix, and postpone the closure of the lacerated perineum to a later date. The performance of both operations at the same sitting is generally an easy matter; indeed, the dexterous operator should be able to add thereto, if necessary, other operative procedures—a curettement and anterior colporrhaphy, for instance—at the same sitting without prolonging the time required for all these operations much, if any, beyond an hour. Frequently, also, it is to the interest of our patient to add one or another required plastic operation to one of the simpler laparotomies, as nothing is looked forward to by women with such great dread as a series of operations to follow each other at greater or lesser intervals of time. The prudent operator will not, of course, for these or any other reasons, be prevailed upon to jeopardize in the least his patient's chances of recovery from a severe or difficult laparotomy. I have, however, a number of times preceded abdominal section for ventro-fixation or for ovarian cystoma by trachelorrhaphy, or followed it by perineorrhaphy, and have not lost a patient upon whom the double operation was performed.

In the operative treatment of prolapsus uteri I have frequently combined ventro-fixation of the uterus with various plastic operations, and it is in these cases especially that the table has proved very serviceable, owing to the possibility of easy and rapid change from the laparotomy to the lithotomy position, and *vice versa*. In April of the present year a patient was sent to me for the operative treatment of a prolapsus uteri. I found a lacerated perineum with a large cystocele and rectocele. The uterus was large, retroverted, and prolapsed in the second degree, the badly lacerated and enormously hypertrophied cervix presenting at the vulva. In addition she was found to be suffering from fungous endometritis. On April 11th I performed curettement of the uterus, amputation of the cervix, anterior colporrhaphy, laparotomy for ventro fixation of the uterus, and colpo-perineorrhaphy in the order named, the time occupied in these operative procedures, inclusive of the necessary changes in the position of the patient, being exactly seventy five minutes. All the wounds healed by primary union, and four weeks after operation the patient left the hospital cured, and remains so to the present day.

This is not the proper place for a full discussion of the subject of combined operations, an urgent topic of the near future, if I mistake not, in gynecology. Suffice it to say that judicious individualization, the personal equation of operator and patient, and the time element especially, are all factors which must be taken into account in reaching a decision in any particular case.

I have also found the table most useful for gynecological examinations. With the patient in the dorsal position as depicted in Fig. 4, the plate supporting the buttocks can be elevated to any desired height. This elevation causes the abdominal viscera to gravitate toward the diaphragm, and by strongly flexing the thighs relieves the tension of the abdominal walls. Conditions are thus established most favorable to an easy and thorough exploration of the pelvic contents by bimanual palpation. The advantages of this position in the examination of difficult cases must be tested to be appreciated.

To recapitulate briefly, the table here described possesses the following characteristics:

It is a complete laparotomy and general gynecological operating-table, as well as a useful examining-table.

It meets the requirements of modern antisepsis in material and construction.

As a laparotomy table it permits of free irrigation of the abdomen, without and within, without wetting the clothing of the patient or operator.

In the employment of elevation of the pelvis—the Trendelenburg posture—it furnishes facilities for almost instantaneous change, as often as desired, to any position between the horizontal and an inclination of 45°, and permits of easy rotation for adjustment to the axis of light.

As a general gynecological operating-table it enables the operator to raise or lower the field of operation at will, and to dispense with all superfluous accessories, such as leg-crutches, straps, and perineal cushions.

The facilities for rapid interchange between the laparotomy and the lithotomy positions, renders the table especially serviceable in the performance of combined operations.

My thanks are due to J. Reynders & Co., 303 Fourth Avenue, for patient endeavor to meet my wishes in the construction of the table.

POLYPUS OF THE MALE URETHRA.

By HERMANN GOLDENBERG, M.D.,

NEW YORK.

THE *New York Medical Journal* of May 9, 1891, contains the report of two cases of polypi of the male urethra. Since then I have had the good fortune to observe another case, which I now present to the readers of the MEDICAL RECORD, as it is interesting from several points of view. The history of the case is as follows:

M. B——, a married man, whose wife and two children show no physical taint, is thirty-six years of age. He had in his youth a number of attacks of gonorrhœa, which were seemingly cured. Two years ago he experienced, for the first time, a slight pain during micturition, which gradually grew worse and exacerbating on excesses in Baccho or Venere. After a while he began to have pain during cohabitation, and of late the feeling "as though some one pricked him with a pin in the glans." He also suffered from frequent painful pollutions, headache, and nervousness and a continual desire to urinate. Furthermore, he could not empty his bladder as soon as desired, but was obliged to wait some minutes before the urine would come. The stream of urine was thinner than normal and he had a more or less copious urethral discharge, which last was the symptom that troubled him most.

When the patient first came under my observation he had a profuse purulent discharge. The subjective symptoms were at this time aggravated. It was supposed that the patient, who did not deny having had extra-matrimonial intercourse, was suffering from a fresh infection, and he was accordingly treated with retrojections of a solution of permanganate of potash (1 to 1,000), under which treatment the discharge ceased, except that there was always a drop at the meatus in the morning. His urine was clear, free from albumin and sugar. There were, however, a large number of "gonorrhœal threads." On examination of anterior urethral canal with bougies à boule and Otis's urethrometer no narrowing could be shown. On entering the posterior urethra with the sound a slight resistance was detected, which was, however, attributed to spasm of the musculus compressor urethræ. Ocular examination with the endoscope, under cocaine, revealed the following: There were a few granulations in the pars bulbosa, the anterior part of the urethra being normal. The posterior urethra was with difficulty brought into view, owing to a resist-

ance which was not easily overcome. The resistance was found to be due to a growth made up by a mass of polyps which appeared plainly in the field of vision. It was located in the membranous part, growing from the lower wall by a broad pedicle. It was about 3 ctm. long, 2 ctm. broad, and 1 ctm. thick, and divided, like a cauliflower, into three or four parts of equal size, closely pressed together. The surface of the growth was smooth, and of a white, epidermis-like color, sharply contrasting with the red, inflamed, surrounding tissue. It was slightly movable, and bled when touched with the probe. The diagnosis of papillomata, made by me at the time, was confirmed later on by Dr. Willy Meyer, who saw the case in consultation.

At first I intended to remove this papillomatous growth by a method which had proved very useful in a former case of polypus of the anterior urethra. It was by passing the endoscopic tube up to the polyp, and then—by a sudden push, to slice off the growth with the sharp edge of the tube. On second thought, however, this method struck me as applicable only when the growth is located anteriorly, so I abandoned it. The success of the method depends on the ability to stretch the penis tensely over the endoscopic tube, so that the polypus may be clearly cut, without danger of injuring the surrounding tissue After an unsuccessful attempt to remove the tumor with the so called "endoscope carunculotome," the ordinary urethral polypus forceps was employed and the growth partially removed. The operation was completed by Oberlaender's "tampon ecrasement," and the base touched with a twenty per cent. solution of argentum nitricum. Oberlaender's method is practical and absolutely harmless. It is carried out as follows: Two small cotton tampons, or a single large one, firmly attached to a cotton carrier, are introduced through the endoscope, pressed into the papillomatous mass and pushed about forward and backward and laterally, thus wiping the growth away from the surrounding tissue. The penis must be tensely stretched over the endoscope while the operation is being performed. In the case described, it was possible, by these means, to entirely remove the growth. The etiology, pathology, and symptomatology of urethral polyps were spoken of by me in a former article (*New York Medical Journal*, May 9, 1891).

In conclusion, let me again call attention to the value of the endoscope in the diagnosis and treatment of urethral diseases. The patient whose case I have related could not have been cured without its aid.

P.S.—The patient visited me four months after the operation and still remained cured; urination and cohabitation have been painless, and he has had no pollutions. The discharge stopped and the general health is excellent. On endoscopic examination no trace of the former trouble could be found.

26 East Sixty-second Street.

New Material for the Dime Museums.—A Mexican journal recently published, with wood-cuts, the account of two persons, living near Morelia, who had attracted considerable attention. One was a child, three years of age, who had a dermoid tumor on the buttock resembling a face. There was a cavity containing two incisor teeth, and above it two depressions containing fleshy caruncles like eyeballs, covered with eyelids, and above them are some hairs like eyebrows. The other case was a man, aged twenty two, who had a tumor the size of a man's head, to the left of the lower part of the spine. This was opened and found to contain the deformed leg, and possibly other parts of the fœtus. The surgeons thought that they had felt the body and head, but as the man was apparently sinking under the chloroform, it became necessary to suspend the operation. The child was the more notable of the two in popular estimation, for it was said that whenever the natis was exposed the face seemed to look at the observer with a sardonic grin that was most soul-stirring.

Progress of Medical Science.

Still Another New Antiseptic—Europhen.—The latest addition to antiseptic remedies is put forward under the fancy name Europhen. This substance is an iodine compound somewhat allied to aristol, containing 27.6 per cent. of the antiseptic element in combination with isobutylcresol. It is described as an amorphous yellow powder, resinous to the touch and adhering to the mucous membrane or skin much more readily than iodoform; its odor is described as peculiar and aromatic, reminding of saffron. In water and glycerine it is not soluble, but readily so in alcohol, ether, chloroform, collodium, traumaticin, and fixed oils. The oleaginous solution is said to be suitable for subcutaneous injection after filtering. Its great advantage over iodoform is said to be that it is much more bulky, so that a given weight will cover five times as much wound surface as the same quantity of iodoform. At the same time, of course, it has an advantage in point of odor.—*The Provincial Medical Journal.*

Salol in Infantile Diarrhœa.—Dr. Weber says that salol manifests its antiseptic properties most markedly in infantile diarrhœa. It is this peculiar quality which renders it superior to many other remedies. Another advantage is the rapidity with which it acts, the vomiting and diarrhœa ceasing in twenty-four hours. Dr. Weber's formula is as follows:

℞. Salol..... gr. iij.
Tinct. opii..... ♏ j.
M. Ft. tal. chart q. s. Sig.: One powder twice daily.

Of course, the amount of laudanum and salol is to be adapted to the age of the patient, especial care being necessary in the use of the former.—*Gazette des Hôpitaux.*

The Treatment of Furunculosis.—Dr. Viel says that the first aim of such treatment should be to destroy the pyogenic coccus in the skin by anti-parasitic remedies before necrosis of the tissue has taken place. If this necrosis has already taken place, then the separation of the necrotic mass and the expulsion of the pyogenic cocci should be accelerated as much as possible. The next aim should be to prevent by injections a new formation of boils. Lastly, the system should be prepared to resist a new invasion of the cocci. The author says that it is rarely possible to fulfil the first condition, and when once the invasion of the pyogenic cocci has produced visible alterations, such as swellings, nodes, or vesicles, necrosis has occurred, and the glandular secretory tract is occluded by pus. This prevents any antiseptics which have been applied to the skin from penetrating to the pyogenic cocci at the fundus of the gland. It is, therefore, impossible for the carbolized mercurial plaster of Unna, the concentrated spirituous solutions of boracic acid recommended by Lowenberg, and many other applications, to do any good. The injection of a three per cent. carbolic acid solution, and the introduction of a wire armed with nitrate of silver, are most painful, and, after all, uncertain. In speaking of the next condition of treatment the author decidedly recommends the old method of hot poultices. He considers that no remedy leads so quickly and certainly to the desired result. To prevent infection of the neighboring tissues he recommends washing the skin with cotton wool dipped in a one per cent. solution of corrosive sublimate, or, when the skin is very sensitive, of a four per cent. aqueous solution of boracic acid, before the application of each poultice. At night the boil is covered with a paste of equal parts of zinc and vaseline, with four per cent. of boracic acid on lint. He also recommends that very indolent boils should be opened, and thinks that it is wrong to squeeze them too soon. The paste also serves to guard the neighboring glands from infection. When a bath can be borne, the author prescribes sublimate baths. He gives his patients highly nourishing food, and, when they are anæmic, preparations of iron.—*The Lancet.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, November 14, 1891.

A NEW THEORY OF THE FUNCTIONS OF THE CEREBELLUM.

IN the present state of our knowledge, or rather ignorance, concerning the function of the cerebellum, it is interesting at least to note the various theories suggested concerning it, and it may be useful as well, since it is by comparing the different theories, and weighing the evidence brought forward in support of each, that we shall finally arrive at definite knowledge concerning this mystery of the nervous system. Since Flourens's time it has been pretty generally believed that the cerebellum has a purely motor function, and although it is not now regarded as a co-ordinating centre, still this observer's dictum, that a man "no more thinks with his cerebellum than he does with his diaphragm," is still accepted by many as true. Recently, however, Dr. Courmont, of Lyons, was led, during the course of a clinical study, to look more closely into the question of cerebellar physiology, and the result of this investigation has caused him to reject the previously accepted view of its motor function as incorrect. The statement and arguments for his theory, which is substantially that put forward rather timidly by Jessens in 1869, but which found little acceptance among physiologists, are contained in a book now in press, advance notice of which is published by Professor Folet in the *Bulletin Médical*, No. 45, 1891.

Briefly stated, Courmont believes that the cerebrum and cerebellum are similar in function as well as in structure. Just as the cerebrum is not only a motor organ, but the seat of cogitation as well, so the cerebellum is a centre for the registration of certain impressions, and for the origin of various psychical manifestations. The cerebrum is the seat of the higher mental faculties, such as thought, judgment, comparison, etc., while the cerebellum is that of the unreasoning mental processes, as love, hatred, joy, sorrow, etc. The one is the organ of sense, the other of sentiment.

This theory is a much more pleasing one certainly than that of co ordination, and Dr. Courmont puts forth some well-reasoned arguments in support of it. We cannot go very far into these arguments in this place, but shall quote only the main points of his theorem, referring the reader to the work itself, or to the review of it in the journal above mentioned, for a fuller exposition of the subject.

The first argument is the anatomical one, that the cerebellum is similar in its general construction to the cerebrum, and though the latter is much larger and of more complicated arrangement interiorly, yet the former is relatively richer in gray matter, which is the organ of the psychical functions. It may also be noted that the cerebellum in women, in whom, with all gallantry it may be said, sentiment is relatively more developed than reason, is larger in proportion to the cerebrum than it is in man. Again, the motor fibres from the cord pass forward and enter the cerebrum, while the sensory fibres incline backward and pass into the cerebellum. Kölliker, indeed, noted these anatomical peculiarities, and remarked that they ill agreed with the modern theories relating to the motor functions of this portion of the encephalon.

Use is also made of incidental testimony furnished by physiological experiments performed with other objects in view. Thus, it was noticed by Vulpian and Ferrier that animals deprived of both cerebral hemispheres might yet experience painful sensations and give expression to various emotions—a conclusive proof, the author holds, that the remaining intra-cranial structures, the cerebellar lobes, must be the seat of these emotions.

The main facts, however, upon which Dr. Courmont relies to establish the correctness of his theory are those furnished by clinical study and corroborated by post-mortem examination. It was the study of a case of puerperal mania which first led him to doubt the correctness of the prevailing theory of the cerebellar functions. The woman was apparently perfectly rational when speaking upon matters of fact, but became at once delirious whenever a word was spoken suggestive of sentiment or affection. If these two fundamental faculties of understanding and sentiment resided in cells of the cerebral cortex, it was difficult to understand how a circulatory disturbance such as this could affect one set of cells and leave the adjacent ones in their normal state. It was thus that he came to the belief that the cerebellum was something more than a mere regulating switch-board for motor impulses. Dr. Folet cites a few of the clinical observations found by the author in a diligent search through the literature of the past several years, in which autopsy showed lesions of the cerebellum. One case was that of a woman, who was morbidly timid, the least thing sufficing to arouse her fears, which, in her childhood, would be expressed by screams and weeping, later by a simple trembling and flight. Yet in other ways she was rational enough, and could converse connectedly with anyone of whom she had learned not to be afraid. She had not a trace of sexual feeling. On autopsy there was found to be an absence of one-half of the cerebellum. A second case was that of a child, who had always exhibited an utter indifference to everything, expressing no pleasure and no pain, yet possessing normal muscular power, and replying sensibly, though in monosyllables, to any question put to her. Upon her death, at the age of eleven, there was found to be a complete absence of the cerebellum. A man died at the age of thirty-nine, who had been regarded during life as an idiot; yet he had a high degree of a certain form of intelligence. He escaped six times from the asylum in which he was confined, making his way out by means of false keys which he fabricated himself. His time was passed chiefly in reading the various reviews, and it was stated that he had a ready and sure

wit in everything relating to concrete matters. He was, however, without any sentiments of honor, affection, gratitude, or the like; was a liar, a thief, and in every possible way immoral. On autopsy he was found to have had a very minute, though well formed, cerebellum.

In a number of experiments made upon rats M. Courmont found that when the cerebellum was removed these animals became profoundly apathetic, and showed neither fear nor anger when disturbed. Yet they were not in a stupor such as is seen after removal of the cerebral hemispheres, for they could walk about, and would approach of their own accord the vessels containing food and water. In those in whom only a part of the hind brain was removed, inflammation of the remaining portions taking place, there arose a state of exaggerated impressionability, the slightest noise sufficing to excite them beyond measure.

A number of arguments, in their way corroborative, are drawn from comparative anatomy, it being shown that the cerebellum is developed in different orders of the animal kingdom in exact proportion to the existence in them of the affections. Thus reptiles and fishes, in whom the sentimental faculties may be regarded as barely existent, the cerebellum is almost rudimentary. It is most developed in the ray and the dog-fish, and these, of all fishes, are precisely the ones that betray the existence of some affection in the care which they take of their young, and in the fact that the male and female couple. Next to man, the dolphins, seals, sea-lions, and other marine mammifers have the best-developed cerebellum, and this agrees with the fact that they are among the most sociable and affectionate of animals. If the cerebellum were the organ of muscular co-ordination, it ought to attain its greatest development in those animals that are the most active; yet in the squirrel it is less developed than in most other mammals.

There is much more that is interesting in Dr. Courmont's argument, as foreshadowed in the review by Dr. Folet, but we have quoted enough to show that the author is not wholly carried away with a theory, but rests his belief upon facts which he believes to be convincing, even though others may not be ready to accept all his conclusions.

THE KNEE A DISTINCTION OF SEX.

The difference of weight in the brains of men and women has long been a source of deep interest to all who discourse of equality and rights. Those extra ounces remain more or less a stumbling-block to the unwary. Metaphysical justice refuses to regard them other than iniquitous. Yet certain structural differences escape such close scrutiny, notably that of the knee.

The structure of the knee feminine constitutes in itself a permanent disability for many masculine pursuits. The knee-joint in women is a sexual characteristic, as Dr. Ely Van De Warker long ago pointed out. Viewed in front and extended, the joint in but slight degree intercepts the gradual taper into the leg. Viewed in a semi-flexed position the joint forms a smooth, ovate spheroid. The reason of this lies in the smallness of the patella in front and the narrowness of the articular surfaces of the tibia and femur, and which in man form the lateral prominences, and this is much more perfect as part of a sustaining column. Muscles designed to keep the body fixed upon the thighs in an erect position, labor under the disadvantage of shortness of purchase, owing to the short distance—compared to that of man—between the crest of the ilium and the great trochanter. A man has a much longer purchase in the leverage existing between the trunk and extremities than a woman. The feminine foot, comparatively speaking, is less able to sustain weight than that of man, owing to its shortness and the more delicate structure of the tarsus and the metatarsus. Women are not well constructed to stand many hours consecutively and every day. It is safe to affirm that they have instinctively avoided certain fields of skilled labor on purely anatomical grounds, in which the smaller quantity of brain-substance proves less an adverse factor than the shallow pelvis, the peculiarity of the knee, and the delicate nature of the foot. These, as parts of a sustaining column, undeniably leave something to be desired. Even the right to vote would not confer on womankind the right to be soldiers. Equality, it appears, is quite as much an affair of the knee as of brains.

HEART DISEASE AND PELVIC LESIONS.

According to a recent pathological study by Dr. W. W. Potter, of Buffalo, pelvic inflammations and their remaining exudates constitute about one-third of diseases treated by gynecologists. The pelvic organs have an enormous blood- and nerve-supply, which is at once their weakness and their strength. The condition of the heart and blood-vessels, together with that of the nervous system, necessarily exercises important influence upon the pelvic organs, both in health and disease. Fothergill has earlier noted the close relationship of functional cardiac troubles and disturbances of pelvic tissues.

The question of coexisting organic heart disease and pelvic lesions secured attention from Nevins some time ago, and his clinical observations are now on record. It remained for Williams, of the Edinburgh University, to contribute to the literature of the subject the clinical history and post-mortem examination of sixty-one consecutive cases. This report, in a small way, is a reply to inquiries as to what proportion of women needing gynecological aid suffer from organic valvular disease of the heart; from what form; what proportion with pelvic lesions present also coexistent valvular difficulty; and what expression of pelvic abnormality is most frequently found associated with organic heart affections.

About one-fourth of these cases presented during life symptoms of some form of valvular disease. Of this number 11.4 per cent. suffered from mitral stenosis alone, 8.2 from mitral and concomitant aortic lesions, and 4.9 per cent. from pure aortic difficulties. Mitral disease existed in eighty per cent. of all with organic valvular lesion, this being the commonest form of organic heart-trouble among women. The most frequent pelvic lesions are pelvic peritonitis, cellulitis, and catarrh of the cervix. The tables given in Dr. Williams's paper (*Edinburgh Medical Journal*, November, 1890) are carefully arranged and of great interest. According to these, endocervicitis is the most frequent pelvic lesion coexistent with organic heart disease, and next in frequency are con-

gestive or inflammatory conditions of the uterus, tubes, and ovaries. In considering whether valvular or pelvic lesions develop first, the author states that the majority of these women were suffering from evident heart-trouble when admitted to the gynecological clinic, and that two had been in the hospital years before for the treatment of cardiac disease.

MYXŒDEMA AND EXOPHTHALMIC GOÎTRE.

In Byrom Bramwell's "Atlas of Clinical Medicine," Volume I., Part I., are contrasted the symptoms of myxœdema and exophthalmic goître. In many respects the clinical features of each are the direct opposite of the other. Their chief points of resemblance consist in the fact that in both the thyroid gland is affected, and that both diseases are more frequent among women than men. In myxœdema the onset is usually slow and insidious, while exophthalmic goître frequently develops suddenly. Thirty is about the earliest age at which myxœdema appears. Exophthalmic goître most often develops between the ages of fifteen and twenty-five. In myxœdema there is atrophy and degeneration of the thyroid, diminution or abolition of its function, subnormal temperature, sensations of chillness, skin dry and harsh, increased electrical resistance, constipation, amenorrhœa usually, diminished emotional activity, and slowness of all nerve-processes. Increased temperature, diminished electrical resistance, soft, moist skin, and increase of perspiration, menorrhagia, attacks of diarrhœa, emotional excitability, and general nervousness, are all symptoms of exophthalmic goître. The degeneration of the thyroid in myxœdema, Victor Horsley suggests, may be secondary to some change, at present unknown, in the nervous system—secondary to some unknown primary nerve lesion. This may be also true of exophthalmic goître.

THE COLLAPSE OF THE "GOLD CURE" FOR DRUNKENNESS.

Despite a famous adage to the contrary, it is the expected that most frequently happens; and under this head we must put the death, in a drunken spree, of the leading convert to the Keeley Institute and its methods.

Two or three months ago there appeared in the *North American Review* a fervidly eloquent description of Keeley, his treatment, and his wonderful cures. The writer, an ex-patient, not only believed himself cured, but knew it with an intensity of conviction that was almost pathetic. Those reading this article could see that it expressed an exaltation of feeling which was hardly normal, and which was bound to be followed sooner or later by a relapse.

Within barely nine months of the Keeley "cure," the patient entered upon a carouse of unusual length, and finally died from its results.

It is a most sad and tragic story, so sad that one feels little inclined to moralize, and least of all to say, "We told you so." The story carries its own lesson. It is the beginning of the end of the Keeley method; it shows what has all along been asserted, that the man possesses no specific, and that his treatment is mainly a moral and hypnotic one.

Of course his adherents take refuge in the statement that he does not pretend to cure all cases, and that about five per cent. relapse. There is not the slightest proof, however, that only five per cent. do relapse. As for the further assertion, that some patients while cured may get the disease again, it is a silly quibble not worth discussing.

We believe most thoroughly in mental and moral therapeutics for the inebriate; but we protest against giving credit of cures by such means to any inert drug or to any other "Something" which is kept as a quackish secret. The charlatan produces wonderful cures for a time, but in the end his work tends to injury and disaster.

VEGETARIANISM AGAIN.

A lady correspondent of one of our daily papers makes urgent inquiries as to where the vegetarians are, and expresses a desire to form an association and start again this phase of dietetic reform.

To the inquiring mind of the would-be vegetarian we would like to submit the following letter, a portion of which we have reprinted before. The author, Dr. Alanus, gives his reasons for abandoning vegetarianism, and says:

"Having lived for a long time as a vegetarian without feeling any better or worse than formerly with mixed food, I made one day the disagreeable discovery that my arteries began to show signs of atheromatous degeneration. Particularly in the temporal and radial arteries this morbid process was unmistakable. Being still under forty, I could not interpret this symptom as a manifestation of old age, and being, furthermore, not addicted to drink, I was utterly unable to explain the matter. I turned it over and over in my mind without finding a solution of the enigma. I, however, found the explanation quite accidentally in a work of that excellent physician, Dr. E. Monin, of Paris. The following is the verbal translation of the passage in question: 'In order to continue the criticism of vegetarianism we must not ignore the work of the late lamented Gubler on the influence of a vegetable diet on the chalky degeneration of the arteries. Vegetable food, richer in mineral salts than that of animal origin, introduces more mineral salts into the blood. Raymond has observed numerous cases of atheroma in a monastery of vegetarian friars, among others that of the prior, a man scarcely thirty-two years old, whose arteries were already considerably indurated. The naval surgeon Treille has seen numerous cases of atheromatous degeneration in Bombay and Calcutta, where many people live exclusively on rice. A vegetable diet, therefore, ruins the blood-vessels and makes prematurely old, if it is true that man is as old as his arteries. It must produce at the same time tartar, the senile arch of the cornea, and phosphaturia.' Having unfortunately seen these newest results of medical investigation confirmed by my own case, I have, as a matter of course, returned to a mixed diet. I can no longer consider purely vegetable food as the normal diet of man, but only as a curative method, which is of the greatest service in various morbid states. Some patients may follow this diet for weeks and months, but it is not adapted for every-

body's continued use. It is the same as with the starvation cure, which cures some patients, but is not fit to be used continually by the healthy. I have become richer by one experience, which has shown me that a single brutal fact can knock down the most beautiful theoretical structure."

We submit the foregoing statements to the lovers of vegetables, because they show that vegetarianism is not a sure and simple road to health and longevity. We do not, however, find ourselves so completely convinced as does Dr. Alanus, that the premature hardness of his temporal arteries was due to his diet alone. Perhaps he ate too much; for this we are sure is a more certain cause of arterial sclerosis than any special diet. In fact, it is still the custom to put cases of Bright's disease on milk and vegetables, as being more promotive of low arterial tension.

All experience shows that temperance in eating, and a good cook, are better than systems of diet in securing health and longevity.

THE GEORGIA BILL TO PREVENT DRUNKENNESS AMONG PHYSICIANS.

We congratulate our Georgia medical brethren on the fact that they have a Governor who has more sense than their Legislature, and that the said Governor has vetoed the bill to prevent drunkenness among physicians. The ground taken by him was essentially that which we took in our criticism of the matter, viz., that the law had no right to make drunkenness a crime in one class of citizens and not in another. The law can make physicians responsible for what they do while intoxicated. This is quite proper, and is the law essentially in several States. The law can also make it a crime for any and every man to get drunk; but it is invidious to select druggists and physicians.

We trust that hereafter the physicians of Georgia will keep a little closer watch on their Legislature, and see that no more such foolish laws are enacted. The State Society should have a committee on legislation, and give it money enough to look properly after medical affairs.

THE ABUSE OF POSTAL PRIVILEGES.

We would respectfully call the attention of the Post-Office authorities to the letter of Professor Flint in the present issue of the MEDICAL RECORD. The charges made are of a grave character, and coming as they do from such a responsible source demand the most thorough investigation.

The Medical Society of the State of New York.—The next meeting of the Medical Society of the State of New York will be held at Albany, February 2, 3, and 4, 1892. Dr. Seneca D. Powell, 12 West Fortieth Street, New York; Dr. James D. Spencer, of Watertown; and Dr. Franklin Townsend, 2 Park Place, Albany, have been appointed the Business Committee. Any communications regarding papers or any matter pertaining to the Society which should properly come before the Business Committee, should be addressed to Dr. Seneca D. Powell, 12 West Fortieth Street, New York City.

News of the Week.

Gynecologists and Happy Homes.—The following is the interesting preliminary "whereas" of a series of resolutions advocating the organization of a new gynecological and surgical society:

"*Whereas*, The happiness of our homes and the welfare and perpetuity of future generations depend upon the physical as well as the moral status of women."

After some further whereases the following resolutions were adopted:

"*Resolved*, That we, the undersigned physicians, do hereby pledge our hearty co-operation and personal support in the organization and perpetuation of a society to be known as the 'Western Association of Obstetricians and Gynecologists.'

"*Resolved*, That the members of this Association shall consist of such members of the profession (regular) who are giving special attention to the practice of obstetrics and gynecology, who reside in the following States and Territories, to wit: The Missouri River cities of Iowa and Missouri; the States of Kansas, Nebraska, and Colorado; New Mexico, Indian Territory, and Oklahoma.

"*Resolved*, That the meeting for the organization of this Association shall be held in the club-room of the Copeland Hotel, in Topeka, Kan., Tuesday, December 29, 1891, at 3 P.M."

The Frequency of Infantile Convulsions.—Dr. G. L. Walton has found that out of 1,000 children, taken consecutively at random from all classes of society, 11.1 per cent. have been found to have a history of infantile convulsions. Among epileptics whose epilepsy did not begin in infancy, seven per cent. had infantile convulsions

The Medical Attendant of the Late Mr. Parnell was announced by cable to be the celebrated neurologist, Dr. W. R. Gowers; English medical journals state that it was just plain Mr. Jowers. Mr. Parnell died of rheumatism and rheumatic hyperpyrexia.

Dr. Koch's Tuberculin.—A telegram from Berlin announces that Dr. Koch published in the *Deutsche Medizinische Wochenschrift*, on October 22d, a further communication on tuberculin, from which it results that, by adding to tuberculin alcohol of sixty per cent., a deposit is formed, which Koch considers to be as nearly as possible the active principle of tuberculin. In therapeutic action this purified tuberculin does not differ materially from the original preparation.

Among the most Valuable Literary Gifts to Professor Virchow, on his seventieth birthday, were two collections of hitherto unpublished scientific researches and essays. The first collection was the work of Virchow's former and present assistants. Professor O. Liebreich presented the volume—a handsome quarto containing contributions by Hoppe-Seyler, v. Recklinghausen, Klebs, O. Liebreich, M. Roth, Salkowski, J. Orth, Jürgens, Grawitz, O. Israel, Langhans, and David Hausemann. The other collection is in the shape of three goodly volumes. Among the authors of the fifty-four papers are: Sir Joseph Lister, Sir James Paget, Horsley, Semon, Pio Foà, Bizzozero, Sangalli, Marchiafava, Celli, Popoff, Ivanowsky, Wood, Jacobi, Bouchard, Metschnikoff, Minra, Stockvis, Ret-

zius, Ackermann, Gerhardt, Leyden, Nothnagel, Rindfleisch, Senator, v. Ziemssen, Ziegler, and Hans Virchow. Among American contributors were Dr. A. Jacobi and Dr. H. C. Wood.

Father Mollinger, of Troy Hill, Pittsburg, priest, thaumaturgist, prophet, and medicine-man, who has accumulated $300,000 from his miraculous cures, is in disgrace (*Physician and Surgeon*). The inevitable Nemesis which awaits chicanery has come from the source which more than any other sustained the reverend father's sensational pretensions—the lay press. The so-called cures have not materialized. In excuse for Mollinger's practices it is pleaded that he is a regularly graduated practising physician, and not only "lays on hands" but gives medicine. This does not excuse the ceremonies of Saint Anthony's Day, when numberless poor ignorant people sacrificed their property and travelled hundreds of miles for relief of imaginary or incurable ailments. A professed follower of Luke, the "physician beloved" of Jesus Christ, can hardly justify himself in such procedures.—*Medical Standard.*

Hydrophobia and Syntax.—The good citizens of Connecticut have been considerably alarmed at the prevalence of hydrophobia among the dogs of the State. The following remarkable notice appeared in the columns of a Farmington journal: "By notice elsewhere it will be seen that any persons owning a dog in the town of Farmington are notified that they must be properly muzzled."—*Medical Record.*

Which reminds us of the notice the Georgia farmer posted on his premises: "If any man's or woman's cow or bull gits in this yere pastur, his or her tail will be cut off, as the case may be."—*Atlanta Medical and Surgical Journal.*

St. Mark's Hospital, New York.—Sir Edwin Arnold gave a reading in aid of this hospital. The amount was $1,203.73.

The Howard University Medical Department graduated Miss Eunice V. Shedd and other colored female physicians, in place of Harvard University, as printed in the MEDICAL RECORD. Dr. Reyburn, who kindly sent us the information, is correct when he suspects that the error was due to his bad penmanship.

The Orton Prize.—At the annual meeting of the New York State Medical Association, held in New York on October 28th to 30th, the committee on the J. G. Orton prize of $100 for the best short popular essay on some subject connected with practical sanitation, reported that ten essays had been submitted in competition. The prize was awarded to Dr. Howard Van Rensselaer, of Albany, N. Y., the title of the essay being "Impure Air, and the Ventilation of Private Dwellings."

The Proclivity of Women to Cancerous Disease.—Dr. Snow says that the number of women who apply at the Cancer Hospital is twice as great as that of the men, and this notwithstanding that the cases of cancer of the lip and tongue are almost all males. This excess of females is due to the prevalence of malignant disease of the uterus and mamma. He then asks why these organs should be so frequently attacked. His answer seems to be threefold: First, these organs are rich in cell-elements. Second, they are frequently exposed to irritation. Third, their normal condition and nutrition are interfered with by circumstances which he considers are more or less directly the result of what is called civilized life. Of these he specially blames constipation, over-pressure at school, the abuse of tea, and tight-lacing.

In Memoriam: Dr. Fordyce Barker and Dr. Abram DuBois.—The New York Academy of Medicine devoted the entire evening, November 5th, to the memory of ex-President Dr. Fordyce Barker, and of its first benefactor, Dr. Abram DuBois. The eulogies were read by Drs. W. T. Lusk and A. B. Ball.

Reviews and Notices of Books.

THREE THOUSAND QUESTIONS FOR MEDICAL STUDENTS. ARRANGED FOR SELF-EXAMINATION. Philadelphia: P. Blakiston, Son & Co. 1891.

THIS vest-pocket publication covers all the seven primary medical branches, and includes diseases of children as well. After each question are numerals referring for the proper answer to the page of one of the text-books mentioned in the introduction as the authority in that particular topic. Most of the questions are practical. Some might well have been omitted. Interleaves allow additions to the printed lists. The little book is attractively gotten up. A serious drawback to its general use is that it is manifestly intended to advertise the medical text-books issued by the same publishers.

THE DAUGHTER: HER HEALTH, EDUCATION, AND WEDLOCK. By WILLIAM M. CAPP, M.D. Pp. 144. Philadelphia: F. A. Davis. 1891.

THE aim of the book is fully expressed in the title. It is a somewhat difficult task to write a work of this kind which is good for anything. It must go into professional details somewhat in order to be definite enough to afford any actual instruction. On the other hand, there are obvious reasons for not putting into the hands of young women details that savor too much of the physician's office and examining-room. Dr. Capp has hit upon a happy medium, and has written a book free from the least suggestion of coarseness and yet conveying much knowledge which ought to be in every woman's possession.

DIPHTHERIA: ITS NATURAL HISTORY AND PREVENTION. Being the Milroy Lectures of the Royal College of Physicians of London for 1891. By R. THORNE THORNE, F.R.C.P., F.R.S., etc.; Assistant Medical Officer to Her Majesty's Local Government Board. 12mo, pp. 266. London: Macmillan & Co. 1891.

THESE lectures discuss, in the light of modern sanitary science, the much-debated question of the nature and cause of diphtheria. Chapter I. gives the decennial statistics of the disease in the United Kingdom. It is frankly admitted at the outset that our increased knowledge in regard to so-called "zymotic" diseases in general has not been rewarded with information of equal scientific accuracy regarding diphtheria. In England the disease is on the increase, while other filth diseases are decreasing. Of late years it has come to be more and more an urban malady, though still holding its own in sparsely settled districts. Geological conditions have not been shown to hold any constant relation to its origin and diffusion, though Mr. Thorne believes that "surface soil, when considered in connection with relative altitude, slope aspect, and prevailing rainfall has . . . concern in the maintenance and diffusion of diphtheria,

and has very possibly some relation with its beginnings." These conditions often impart to a local throat malady "a specific and infective quality." Much stress is laid upon the general proposition that ordinary epidemics of "sore throat" can gradually grow into true diphtheria. A perusal of the history of various diphtheria epidemics shows that the disease has spread more during the months of excessive rainfall and of comparatively low temperature.

The general position taken is that topographical and meteorological conditions leading to a cold and wet soil and atmosphere are predisposing causes of diphtheria, and that the morbific agent is an "organism with seasonal development, attaining its chief reproductive power in the autumn, the very season when the air is known to be especially charged with fungoid germs."

The author fully admits the powerful factor of pre-existing abrasions of the mouth epithelium from any cause in the etiology of the affection.

Chapter II. treats of the relation of diphtheria to "sore throat" and scarlatina. A careful study is made of the progressive development of the property of infectiveness.

Chapter III. discusses the influence of school attendance in spreading the disease. Interesting statistics are given concerning the relation of compulsory education to the general increase of the disease.

Chapter IV. illustrates the property of milk to diffuse the malady. A moderate position is taken with reference to the etiological importance of the Klebs Loeffler bacillus. Mr. Thorne contents himself with quoting at length the results of Klein's studies, and does not offer any original observations on this point.

Chapter V. treats of general measures of prevention, isolation, and disinfection.

It will be seen from this analysis of contents that the point of view is that of the sanitarian rather than that of the bacteriologist or practising physician. It is well that we should have such an important subject discussed in every possible light. Diphtheria is, perhaps, the disease which we most dread, and the therapeutics of which still flounder about in a sea of uncertainty. We have as yet no specific for it. We shall ward off its ravages by prevention rather than by cure. We regard Mr. Thorne's lectures as a most creditable contribution to literature. They may well be read by everyone practising medicine, for every one meets with cases of diphtheria. His analyses are searching, his reasoning cogent, and his conclusions logical.

De l'Empyème Latent de l'Antre d'Highmore. Étude accompagnée de vingt-deux Observations inédites, recueillies à la Clinique du Dr. Lichtnitz (de Bordeaux). Par le Dr. J. Marcel Jeantz. Bordeaux: Feret et Fils. 1891.

This is a very complete and satisfactory study of the latent form of purulent inflammation of the antrum of Highmore by a close student and accurate observer who has been able to make use of a considerable amount of new material. The work is divided into seven parts, devoted successively to the history of this form of suppuration within the antrum, its etiology, symptomatology, diagnosis, course, and treatment, and concluding with the clinical histories of twenty-two hitherto unpublished cases. The subject is treated of exhaustively, and the book must be regarded as a valuable addition to the already somewhat voluminous literature of this disease.

Les Épilepsies et les Épileptiques. Par Ch. Féré, Médecin de Bicêtre. Avec 12 planches hors texte et 67 figures dans le texte. Félix Alcan, Éditeur. Large 8vo, pp. 636. Paris: Baillière & Cie. 1890.

Féré's large work, though aiming to furnish a systematic account of epilepsy, differs from ordinary works of this class. It contains a large amount of carefully made clinical observations, also many investigations into the physique and psychology of epileptics, particularly such as bear upon the stigmata of degeneration. We know of no work which contains so full an account of the physical condition and morbid physiology of this class. Very interesting facts are given also regarding post-convulsive phenomena.

It is in these fields of clinical study that Féré's book possesses unique and positive value. In the chapter on pathology and pathological anatomy Charlin's observations are quoted, but nothing else new is given. It is something of a relief not to find pages filled with discussions on higher and lower levels, discharging and inhibiting centres, and the other machinery of the evolutionary epileptic hypotheses of which English writers are so fond.

The therapeutic part of the work is disappointing. It contains a list of remedies recommended for epilepsy, but this list is not very critically edited; the author's only original recommendations are the cautery to the scalp in focal epilepsy, and the leaden cap in epileptic headaches. The illustrations and typography of the book are excellent.

Recherches cliniques et thérapeutiques sur l'Épilepsie, l'Hystérie et l'Idiotie. Compte-rendu du service des Enfants idiots, épileptiques, et arriérés de Bicêtre pendant l'Année 1889. Par Bourneville, Sollier et A. Pilliet. Vol. X., avec 22 figures dans le texte et une planche chromo-lithographique. Paris: Lecrosnier et Babé. 1890.

This volume contains a report of the service during the year 1889, therapeutical studies on bromide of gold, bromide of camphor, and picrotoxine, and clinical and pathological studies on myxœdematous idiocy, encephalitis, and hysteria. Bourneville's reports always contain matter of practical and scientific interest and the present one is no exception.

Psychologie de l'Idiot et de l'Imbécile. Par le Dr. Paul Sollier. Avec 12 planches hors texte. Félix Alcan, Éditeur. 8vo, pp. 276. Paris: Baillière et Cie. 1891.

Sollier's work will commend itself to teachers of backward and imbecile children, to physicians who so often have to deal with them, and especially to psychologists, who are now beginning to find out how much can be learned by studying imperfectly developed minds. This book is one of a series called "The Library of Contemporary Philosophy."

On the Medical and Surgical Uses of Electricity. By George M. Beard, A.M., M.D., and A. D. Rockwell, A.M., M.D.; formerly Professor of Electro-Therapeutics in the New York Post-Graduate Medical School and Hospital; Fellow of the New York Academy of Medicine; Member of the American Academy of Medicine; Member of the New York Neurological Society; formerly Electro-Therapeutist to the Woman's Hospital of the State of New York, etc. Eighth edition. With over two hundred illustrations. Pp. xxvii., 788. New York: William Wood & Co. 1891.

This book needs little comment. For the past twelve years it has been an acknowledged authority, and its popularity is evinced by the fact that of the seven previous editions each successive one has been exhausted more rapidly than its predecessor. A like flattering reception doubtless awaits this, the eighth edition, for it is far and away the best one yet published. Changes have been extensive, and the work as it now stands represents the complete and reliable knowledge of electricity. Every thing of value pertaining to the subject is given. The chapters on "Diseases of Women," "Electrical Apparatus," and "Static Electricity" have been recast, additions made to the chapter on "Electro Diagnosis," and many

new illustrations representing practical and important methods of application supply the places of the old ones. Two new chapters are added. One of these, "The Dosage of Electricity," is of especial importance. The failures that so many physicians meet with in the use of electricity are largely due to their ignorance of dosage. The author also calls especial attention to the new chapter on the "Physical and Physiological Activities of the Induced Current," etc. There is no more interesting study in electro-therapeutics than the differential indications for the use of the induction currents of quantity and tension, and in this chapter the subject is discussed to the measure of our present experience. The book is not only a work of exhaustive reference, but the busy practical physician, who cares little for the science and everything for clinical results, will find just what he needs presented by a large variety of illustrations of the various methods of application and by details of more than two hundred cases, including every type of medical and surgical disease for which electricity by any method of application has been used with any encouraging result. Dr. Rockwell has done his work of revision well. He writes clearly and forcibly, and, being a thorough electrologist, scientifically. The publishers likewise have maintained their excellent reputation, and have presented the profession with a book that is a model of the typographical art.

On Painful Menstruation. The Harveian Lectures, 1890. By Francis Henry Champneys, M.A., M.D. Oxon., F.R.C.P.; Physician accoucheur and Lecturer on Obstetric Medicine at St. Bartholomew's Hospital (late at St. George's Hospital); Consulting Physician to the General Lying-in Hospital; Examiner in Obstetric Medicine, Member of the Board of the Faculty of Medicine in the University of Oxford; Examiner in Obstetric Medicine in the Royal College of Physicians, London, and (late) in the University of London. Pp. 88. London: H. K. Lewis, 1891.

The Harveian lectures are always good. The series of 1890, which make up the book in hand, was no exception to the rule. In fact, the lectures were of unusual excellence, and gave the most complete exhibition of a very important subject that the profession has yet had—a subject that is not only of interest to the specialist but to every practitioner, for cases of painful menstruation are daily met with. There are three lectures in the book. The first treats mainly of the physiology of menstruation, but also takes up the subject of dysmenorrhœa in general, giving a description of the several varieties. Lecture No. II. is devoted to membranous dysmenorrhœa, which the author has most thoroughly studied. Its literature is so enormous that it has been relegated to a table which requires a pocket in the book's cover to hold it. The third lecture treats of spasmodic dysmenorrhœa. The work, all in all, is a most excellent one, and deserves careful study.

Transactions of the Medical Society of the State of California. Session of 1891. Pp. 355. San Francisco: W. A. Woodword & Co.

The annual meeting was held in Sacramento last spring, and was of unusual interest owing to a large attendance and the excellence of the papers read. All of them are included in the book under review. They deserve careful reading and a place in the library. All branches of medicine are treated.

Les Fonctions du Cerveau. Doctrines de l'École de Strasbourg, Doctrines de l'École italienne. Par Jules Soury. Pp. 464, 8vo. Paris: Lecrosnier et Babé. 1891.

The author of this treatise has made an industrious study of the progress made in our knowledge of the functions of the brain in the past twenty years. M. Soury is not himself an anatomist but rather a critical scholar, and his work must be judged accordingly. It is particularly valuable in its account of the labors of the Italian physiologists. It will give the reader a good idea in general of our present knowledge of brain functions.

The book is one of a series of histories of the doctrines of contemporaneous physiological psychology.

A Manual of Practical Electro-Therapeutics. By Arthur Harries, M.D., and H. Newman Lawrence, M.I.E.E. Pp. 129. Illustrated. London: Sampson Low, Marston & Co.

This book is No. 3 of the "Nursing Record Series," and upholds the high standard achieved by its predecessors. The authors are leading electricians of the Institution of Electrical Engineers of London, and joint authors of several valuable books. This vouches for the accuracy and value of the work in hand. It treats of the subject in detail and in the simple manner that the beginner can understand. After excellent technical descriptions of apparatus the medical aspect of electricity is discussed. Indications for, and methods of, application are given, and the physiological action of the various currents are explained. A valuable list of books for reference and further study of the subject is also given.

Proceedings of the Connecticut Medical Society. New Series, Vol. IV., No. 4. Pp. 346. Published by the Society.

This valuable book is the report of the ninety-ninth annual convention of the Connecticut Medical Society, held at Hartford, May 27 to 29. 1891. It contains a great number of excellent papers by some of the best men in the medical profession. Articular rheumatism and Koch's lymph receive especial attention, as do likewise the various methods of treatment of pneumonia, scarlatina, and intestinal catarrh. The book reflects great credit on the secretary of the Society, Dr. N. E. Wordin, of Bridgeport, Conn.

The Fire Protection of Insane Hospitals By L. H. Prince, M.D., Resident Physician, Bellevue Place, Batavia, Ill. 4to, pp. 121. Chicago: C. H. Blakely & Co. 1891.

These pages contain some very timely advice on a most important matter. Dr. Prince shows that since 1850 nearly two hundred and fifty people have lost their lives by fire in American institutions for the insane. His chapters describe fire extinguishing apparatus, the alarm, the fire-brigade and its drill, with the utmost completeness. The rules which he has laid down will serve as a guide for the management of all large institutions of every kind.

Transactions of the Texas State Medical Association. Session of May, 1891. Edited by Dr. H. A. West, Secretary. Pp. 278. Galveston. 1891.

An attractive looking volume, covering the usual topics. Our distant brethren in the South have a most prosperous society.

A Curious Impressionability to Electric Lights.—Dr. John M. Currier relates, in the *Medical and Surgical Reporter*, an odd case of a girl, about nineteen years old, not subject to fainting spells on ordinary occasions, who always feels a peculiar sensation on entering a room illuminated with electric lights, but may not faint until she returns home, when an attack of heart-failure will come on and last an hour or more. She never can enter the presence of an electric light without feeling the heart-failure coming on. No other kind of bright light, however strong, has the same effect.

A Case of Death from the Proprietary Mixture Antikamnia is reported (*American Practitioner*). This drug is said to be composed of about eight parts antifibrin and two parts bicarbonate of soda.

Society Reports.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Seventeenth Annual Meeting, held in St. Louis, Mo., October 14, 15, and 16, 1891.

(Concluded from page 551.)

THIRD DAY, FRIDAY, OCTOBER 16TH.

Amputations with Regard to Artificial Legs. — MR. CHARLES TRUAX, of Chicago, read a paper (by invitation) entitled "Are Conservative Amputations Always in the Interest of the Patient?" He said that during the past quarter of a century the development of prosthetical science has advanced with a rapidity unprecedented in the history of the art. The first of the two great causes which stimulated this development may be found in the dreadful carnage and mutilation observed in the late civil war, which left thousands of veterans maimed by the loss of one or more limbs, for whom it was necessary to provide artificial substitutes. Experience and investigation had convinced him that the percentage of favorable cases can be largely increased, provided surgeons will familiarize themselves with the necessary mechanism of ordinary artificial legs and the relations existing between them and the stumps on which they are to be worn and select their point of amputation accordingly.

From a statistical point of view he finds that out of 2,135 tibial amputations reported as being performed between the years 1885 and 1891, 90.7 per cent. resulted in healthy stumps; 3.1 per cent. of stumps upon which compensative appliances could not be worn Of these tibial cases, 962 were seen by the surgeons after they were wearing, or had attempted to wear, an artificial limb, 86.9 per cent. of which walked with an easy movement and a comparatively graceful step. Of 658 tarsal and tibio-tarsal amputations reported at the same time, 82.7 per cent. resulted in sound, healthy stumps; 8.3 per cent. underwent re amputation; while 3.2 per cent. died, leaving 14 per cent., including re-amputation, upon which prosthetical apparatus could not be worn. Of this class of cases 169, seen after attempting the use of compensative appliances, 54.4 per cent. could walk well.

If we can judge from the foregoing statistics, in over 100 cases of each of these classes of operations, we may reasonably expect the death loss to be in favor of tarsal operations as 5.0 to 3.2 per cent.; while the ratio of re-amputations necessary will be in favor of tibial amputations as 8.3 is to 3.1. He recommended surgeons to avoid amputating within three inches of the knee-joint, or between the metatarsal bones and the junction of the lower and middle thirds of the tibia. At all other points they should save all they could, and then they will have done, in every case, the best for their patients.

DR. HENRY H. MUDD, of St. Louis, read a paper on "Intestinal Obstruction," in which he advised early operation.

The Thermometer in Abdominal Surgery.—DR. C. H. DALTON, of St. Louis, read a paper entitled "Temperature No Guide in Peritonitis." So sceptical had he become on the subject that in considering the advisability of an operation in abdominal cases he was no longer guided by the thermometer. He always took the temperature in all cases, but did not let the lack of fever influence him against operation when other symptoms upon which he had learned to place far more reliance would move him in the opposite direction. Surgeons found it difficult to convince the average physician that a violent peritonitis may exist with a normal, or even subnormal temperature, for the teaching by some has heretofore been that sepsis is always accompanied by an elevated temperature.

Several weeks since he was called in consultation in a case of intestinal obstruction in which peritonitis was in full blast. He advised operation and was met with the objection that there could not be much peritonitis with a temperature of 99.5° F. He pointed in vain to the patient's anxious countenance, to the great tenderness on pressure, a distended belly, the vomiting, the pulse, as well as to the fact that purgatives had been tried without avail. The doctor in attendance insisted upon one more dose of salts. It was given. It did not move the bowels, but did move the patient to that place from whence no traveller returns. Time and again he had seen cases of intestinal obstruction with stercoraceous vomiting, rapid pulse, anxious countenance (facies abdominalis), in which the temperature was about normal or even subnormal.

In his earlier experience the lack of fever in abdominal cases puzzled him very much and led him astray in a number of instances. While it is well to remember that fever when present in these cases indicates peritonitis, its absence does not warrant us in saying that peritonitis is not present, and should not blind us as to the actual condition.

Sarcoma of the Dorso-scapular Region.—DR. GEORGE N. LOWE, of Randall, Kan., read a paper on this subject. He reported a case upon which he had operated, the patient, a youth, aged eighteen years, with no history of tuberculosis, carcinoma, or sarcoma, recovering. The object of the paper was to show: 1, The necessity of an early operation in all cases of a malignant growth; 2, that some species of sarcoma are more rapid and destructive in their course than carcinoma, especially the spindle and giant-celled variety; 3, the necessity of having a law to enforce patients so afflicted, as soon as a correct diagnosis can be made, to an early operation, thereby preventing great suffering and prolonging life; 4, that in a sarcoma which has grown to an enormous extent, infiltrating the surrounding tissue at any considerable extent from the main growth with cell proliferation, an operation is almost useless as regards a permanent cure.

Perityphlitis.—DR. W. H. LINKE, of Petersburg, Ind., read a paper on "Appendicitis," and offered the following therapeutical suggestions: "In the commencement of the attack give salines often and liberally till the gut is completely emptied. Advise perfect rest in bed. Forbid any but liquid nourishment. If pain is severe apply counter irritation and dry heat till salines act. If the patient improves, wait. If the pulse grows worse, if the temperature rises, if the pain increases, if the tumefaction becomes larger, if tenderness becomes more marked, operate. At no time give morphine, but consider an increase of pain sufficient to demand relief by opium an imperative, unequivocal, and emphatic indication for surgical interference."

Rheumatism and Gout as Factors in the Causation of Eczema, and the Management of those Conditions, was the title of a paper contributed by DR. A. H. OHMANN-DUMESNIL, of St. Louis. He did not purpose speaking of the etiology of eczema. The only phase which he desired to take under consideration was, in how far rheumatism and gout were concerned in the causation and prolongation of eczema, and what was the proper management of those conditions in order to derive the greatest benefit, so far as the cutaneous involvement is concerned. Naturally this implied that he was about to sustain the position that the conditions named were etiological factors, and such was probably the case. If we took the trouble to examine critically the history, condition, treatment, and results in patients, a mass of evidence would be found which, if it did not constitute absolute proof, bore so much weight with it that the probabilities would all tend to confirm and strengthen the position that rheumatism and gout prolong, intensify, and even cause eczema. He had quite frequently also noted the fact that an acid condition was present in eczematous patients. It occurred too frequently to be regarded as a coincidence. Moreover, a correction of this acid condition finds its good effects reflected in the case with which the cutaneous trouble gave way to proper medication. Whether

such cases were inclined to rheumatism or gout it was difficult to say; but that an excess of acid was found in all of these conditions there was no opportunity of denying. For, if eczematous patients were interrogated in this respect a large proportion of them would speak of acid eructations, pyrosis, and other evidences of the condition.

In regard to the management of gout and rheumatism volumes had been written, and equally good results had been claimed for different methods of treatment. The most powerful alkali to affect the solubility of uric acid was, beyond all doubt, lithia. The urates of that alkali are the most soluble known, and, on that account, a better elimination can be secured. Potash salts rank next in value in regard to their solvent value upon uric acid. The soda salts, while exercising a good influence, are not as valuable in this respect as either of the others; and the magnesia salts are the least effective.

Dr. Enno Sander, of St. Louis, had prepared his well-known lithia-potash water, which fills all the indications required, and which acts not only as an anti-rheumatic, anti-lithic, and anti-gouty mixture, but constitutes a grateful table-water as well. It not only acts as a curative remedy, but, what is of still greater importance, it is a reliable prophylactic. Its composition is as follows:

R. Lithium bicarbonate	gr. xiij.
Magnesium bicarbonate	gr. x.
Potassium bicarbonate	gr. xvj.
Sodium chloride	gr. x.
Carbonated water	℥ xvj.

M. This quantity, one pint, should be taken daily, or the amount increased if deemed necessary.

Conditions occasionally arise in which it will be found that a mixture of salicylate of soda and bicarbonate of soda will effect the happiest results in rheumatism, and occasionally in gout. Given in carbonated water the administration is made pleasant, and the mixture has an effect upon the patient which is refreshing at the time it is taken, and which effects beneficial results in a very short time. When eczema is present the proper local remedies should be applied, and it is astonishing how their action will be accentuated by the internal use of the alkalies as indicated above.

Observations on the Management of Uterine Tumors.—Dr. C. A. L. Reed, of Cincinnati, O., read a paper with this title, in which he said that there are certain solid tumors of the uterus that require no operation. They are for the most part comparatively small neoplasms either interstitial or subserous; they are indolent in growth, and they do not produce alarming symptoms from either pressure or hemorrhage. There are certain other myomata of the uterus that are uniformly recognized as demanding operation. They are for the most part rapidly growing tumors in young subjects; removable fibro-cystic tumors; soft œdematous tumors; large bleeding fibroids, and those growths which give rise to ascitic accumulations.

Dr. Reed offered the following conclusions: 1. That all persistently hemorrhagic uterine myomata, of whatever variety, should be advised to early operation. 2. In young subjects, with multinodular tumors giving rise to alarming hemorrhage, the appendages should be removed when practicable as an alternative for extirpation. But the latter operation should be done whenever the character of the growth will permit of its removal by dangers less than those which would be involved by its continued existence. 3. To those tumors already recognized as demanding operation should be added those of uterine development that are liable to dangerous constriction by the uterine walls and in which their destruction by this means might induce sepsis. 4. All cases of subserous growths, indolent, yet progressive in character, in which the tumor has become a menace to neighboring organs, should, whether hemorrhagic or not, be advised to exploratory incision with reference (1) to removal of the appendages, or (2) of the neoplastic organ. 5. All growing tumors, occurring in women beyond the menopause, should be removed, if possible, by vaginal total extirpation, or, if that be impracticable, by abdominal section. 6. All distinctly operable cases demanding interference should be advised to submit to operation at the earliest practicable moment.

The Etiology and Treatment of Granular Conjunctivitis.—This was the title of a paper contributed by Dr. Francis Dowling, of Cincinnati, O. The author stated that the great rôle which the disease plays in the causation of blindness renders its successful treatment one of the great disiderata of our day. Its great hot beds are in some of the countries of the Orient, owing to the prevalence of whirlwinds of sand and the intense heat and glare of the sun. The malady attacks by preference the poorer classes; the rich and well-fed enjoy a comparative immunity from the disease. It is more frequent in persons between the ages of fifteen and forty-five, and children under six rarely have the disease. It does not become epidemic at a height of over two hundred and fifty metres above the sea level, and it loses its contagious character at this height. Low regions and swamps favor its spread. It is highly contagious; probably three-fifths of the blindness throughout the world is directly or indirectly due to this disease. There is often some special liability on the part of certain individuals to the contraction of the disease, owing to the presence of a special diathesis, or otherwise.

As to the treatment, he had had more success by touching the lids with the mitigated stick of nitrate of silver and then immediately washing it off than with any other remedy. He applies the treatment usually twice a week, and on the intervening days he rubs in an ointment composed of yellow oxide of mercury and atropia. He also corrects any trouble of refraction that may exist, for unless this is attended to the disease will persist under all kinds of treatment.

The disease is now treated in Paris by completely everting the lid and scarifying the granular tissue, then rubbing in with a stiff brush a one to five hundred solution of bichloride of mercury. Cases are cured in this way in four to six weeks that formerly took several years to cure with the old treatment. In outbreaks of the disease in orphan asylums, barracks, etc., the afflicted should be completely isolated from the healthy inmates, and their apartments should be kept absolutely clean and fumigated with burning sulphur at least once a week.

Portal on Placenta Prævia.—Dr. John Bartlett, of Chicago, presented a paper in the form of a review of an obstetrical work, published in Paris in 1682 by Paul Portal. He said the older members of the profession had for years rested in the opinion that it was Paul Portal to whom obstetrical science was indebted for the discovery of the fact that in placenta prævia the after-birth was attached to the womb, and had not simply fallen down over the os, as was taught by writers before his day.

Stricture of the Urethra.—Dr. G. Frank Lydston, of Chicago, followed with a paper on this subject. He was opposed to the general belief prevalent among surgeons that the long duration rather than the severity of a virulent urethritis determined the development of organic stricture. It is not the long continued urethritis that produces a deposition of the adventitious tissue constituting organic stricture. On the contrary, a chronic localized urethritis exists because the stricture or the foundation of it has been determined at some portion of the urethra by the primary virulent inflammation. He claimed that the liability to the formation of organic stricture is directly proportionate to the severity of the primary inflammation. The localization of stricture, the author insisted, was not due, as Sir Henry Thompson and his school assert, to an obstruction to drainage and the retention of the products of virulent inflammation, but to deficient elasticity or distensibility of the canal at certain points. The conditions determining stricture he compared to those prevailing in

a rubber tube about which cords are tied in such a manner that while some actually constrict the tube, others simply prevent its distention. If fluid be pumped through a rubber tube thus constricted or restricted, as the case may be, under a certain degree of hydrostatic pressure, friction occurs at these points. The epithelium is rapidly removed, its vitality being impaired by the virulent poison of urethritis. By and by rapid removal and re-formation of epithelium becomes a cell habit, the resulting formation of cells being of a low grade of inherent vitality. In addition to this change upon the surface of the mucous membrane there are deposited young connective tissue cells in and about the affected point, the result of an attempt on the part of nature to secure rest and prevent strain. These cells the author likened to sand-bags thrown up to prevent a breach in a fortification.

The doctor called attention to a number of interesting reflex phenomena incidental to stricture of the urethra, and referred at some length to the various toxæmic conditions incidental to renal disturbance secondary to stricture, and to that peculiar form of toxæmia incident to the absorption of ptomaïnes from the site of the urethral lesion. He denied the possibility within the limits of safety of using electrolysis in the treatment of organic stricture. He condemned the routine and extreme claims of Newman, and also the other extreme, as represented by Dr. Keyes, who asserts that galvanism, *i.e.*, so-called electrolysis, has absolutely no effect. Dr. Lydston claimed that the effect of galvanism upon organic stricture of the urethra was the same in its physiological character as upon healthy or morbid tissue in any other situation. The author described what he terms *plus* conditions of organic stricture. Thus we have engrafted upon the organic foundation varying degrees of hyperæmia, spasm, and œdema, one or all. These *plus* conditions, he claimed, galvanism, properly applied, would subtract from the organic condition in certain cases, and in so far as this effect was marked the stricture would be benefited. The author denied the possibility of the galvanic current producing absorption of fibro-connective tissue, after it has arrived at the acme of differentiation, by any current which will not destroy the mucous membrane itself; in other words, we cannot control the galvanic current so that it will exert a selective action and remove the abnormal tissue while sparing the normal tissue.

Election of Officers.—The following officers were elected: *President*, Dr. C. A. L. Reed, of Cincinnati, O.; *First Vice-President*, Dr. C. S. Bond, of Richmond, Ind.; *Second Vice-President*, Dr. Thomas Hunt Stucky, of Louisville, Ky.; *Secretary*, Dr. E. S. McKee, of Cincinnati, O.; *Chairman of the Committee of Arrangements*, Dr. Joseph Ransohoff, of Cincinnati, O.

Place of next meeting, Cincinnati; date of next meeting, October, 1892.

Medical Practice in Japan.—The total number of physicians in Japan at the end of 1888 was 40,940; an increase of 61 as compared with the previous year. At the end of 1889 the number was 41,405, which is an increase of 465 as compared with the previous year. This increase is, however, only apparent, as, in proportion to the increase in population of the country there is a falling off in the number of physicians. The total number of midwives at the end of 1888 was 30,860, which was an increase of 997 as compared with the previous year. At the end of 1889 the number was 32,111, which was an increase of 1,251 as compared with the previous year. When compared with the several previous years there is seen to be a gradual but steady increase year after year. The number of hospitals in 1888 was 504, an increase of 48, of which 1 was public and 47 private, as compared with the previous year. In 1889 the number was 573, of which, public hospitals had increased by 3, and private hospitals had increased by 12, as compared with the previous year.—*Sei-I-Kwai Medical Journal*, September 26, 1891.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE HARVEIAN ORATION AT THE COLLEGE OF PHYSICIANS—A DYNAMIC THEORY OF RENAL DROPSY—CORROSIVE-SUBLIMATE BATHS IN THE TREATMENT OF COMPOUND FRACTURES INTO JOINTS—SIR GEORGE HUMPHRY ON THE NEW PATHOLOGY.

London, October 24, 1891.

The oration in honor of Harvey, delivered at the College of Physicians on Monday last, was the 173d of the series. Following 172 previous annual addresses on the same subject it would be unreasonable to expect from the speaker any new material respecting Harvey. On the present occasion, after giving some account of Harvey's personal history, his work, and the time in which he lived, Dr. Dickinson, the orator for this year, proceeded to speak of the results of Harvey's discovery. These were at first not beneficial to medicine and harmful to Harvey, for his practice "fell off mightily." Dr. Dickinson suggested that two observations applied to Harvey's discovery, and to many others, viz., 1, that practice advanced independently of science, and often anticipated its conclusions; 2, that what had been established by practice would hold its ground after the introduction of scientific knowledge by which it should have been abolished. There were many examples of the first of these. Thus, suction-pumps, as Sir George Paget observed, had been at work for hundreds of years before Torricelli showed the true cause of the suction. Gunpowder was invented five centuries before anything was known of oxygen, carbon, or the laws of combustion. Not only was venesection in use before the circulation was understood, but the arm was constricted above the puncture. Transfusion of blood was certainly practised in 1615. Of the second, among the examples cited by the orator were the following: The practice of the second century was still seen in the leeching of the hypochondrium to deplete the liver, though there was no way through; we still cupped the back to deplete the lung; we cupped the loins to relieve the kidneys, and if we succeeded in finding a few insignificant vessels connecting the capsule with integuments, we rejoiced over them, and flattered ourselves that we were the disciples of tradition and science too. Dry cupping furnished another instance of a practice which had survived the theory on which it was based; it apparently had its origin in the ancient belief that the arteries contained spirit which could transpire by the skin.

The first important result of Harvey's work was the completion of it by the discovery of the capillary system by Malpighi, who was born in the year in which Harvey published his famous treatise. The first improvement of immediate utility directly resulting from Harvey's work was the invention of the tourniquet, by which arteries were compressed as distinguished from the veins. Then came John Hunter's operation for aneurism—tying the artery between the sac and the heart. Then, to take no note of lesser advances, auscultation came. Next came the knowledge of the course of emboli. Another Harveian development had no narrower limits than the whole extent of inflammation, or at least as much of it as concerned the capillaries. Dr. Dickinson remarked that were he to look only at a portion of the field presented, and dwell upon the changes in the heart and arteries which Bright in part discerned, and which Johnson, Gull, and Sutton had done so much to amplify and elucidate, he should find enough to show that Harvey had worthy successors in his own college.

The orator then proceeded to speak of dropsy in connection with the Harveian scheme. It was not needful, he said, to remind his audience that many forms of dropsy were simple consequences of impediments to the circulation, and required nothing more than a knowledge of the

course of the blood for their complete explanation. But he would adventure further and endeavor to show that renal dropsy, generally credited with a totally different mode of production, had its association with those which were purely mechanical, and was connected with the attitude of the blood-vessels as well as with the chemistry of their contents. Some forms of dropsy were obviously connected with exaggeration of intravascular pressure. He would endeavor to show that renal dropsy was dynamical as well as chemical, and that it was associated with arterial pressure as the others were with venous, as immediately, though not *ab initio*. Over transudation, such as occurred in renal dropsy, might be hypothetically attributed to three causes—osmosis or dialysis, filtration from pressure, and, as Dr. Waymouth Reid would infer, an action on the part of the blood-vessels analogous to secretion. Where filtration ended and secretion began would be a difficult question to answer, if both were concerned. The secretive theory had been resorted to in consequence of the apparent inadequacy of osmosis to explain the phenomena in question, but it could not be doubted that the paramount agent in moving the liquids of the body, whether along tubes or through their walls, was pressure.

If we looked at the character of the effusions in different kinds of dropsy, certain broad facts presented themselves which appeared to have significance. The chief components of such effusions differed from each other as crystalloid and colloid, the salts crystalloid and highly diffusible, the albumin colloid and slightly diffusible, except under pressure. Under osmosis salts should transude without albumin, under pressure both together. Now whatever the cause of the dropsy, the effusions in the same place were essentially the same. The effusions varied much with situation, little with disease; those into the serous cavities were always rich in albumin, those into the cellular tissue, poor in albumin with equal constancy. When renal dropsy set in the urine was usually below par, but the relation of dropsy with the quantity of urine was not constant enough to explain the process. With obstructive suppression dropsy was usually totally absent, while it was frequently present under the diuresis of diabetes. Anæmia had been thought to be concerned in renal dropsy, but we often saw intense and even fatal anæmia ("pernicious") without any such effusion. With obstructive suppression arterial tension was conspicuously wanting, while death occurred by asthenia or syncope. Low blood pressure, with no dropsy where it might otherwise be expected, was at least suggestive of the need for more facts. In acute nephritis, where the urine was only scanty, not suppressed, we saw high blood-pressure, and together with this dropsy. Want of urine did not alone and of necessity cause renal dropsy; increased arterial tension would seem to be a necessary intermediary, at least of this variety of it. Such increase of tension, beginning with the earliest stage of nephritis, accompanying the œdema and increasing with it and the disease, had long attracted notice. A conclusive proof of its presence was the hypertrophy of the left ventricle, even in the acute forms of the disease. Hypertrophy of the left ventricle and of the muscular coat of the arteries must be equally accepted as evidence of an obstacle ahead. Where was the arterial exit impeded? Renal dropsy, presumably, depended on excess of exudation, not deficiency of absorption; this could scarcely occur elsewhere than from the capillaries, whose walls alone were adapted to the process. If the primary obstacle were in the arterioles, the blood must be in a measure shut off from the capillaries, the pressure on them reduced, exudation from them lessened, and the view of renal dropsy he was about to submit abandoned. It had been urged that the capillaries were not muscular, but it had been shown by Roy and Graham Brown that they were contractile; we could not doubt, also, that the blood might acquire peculiarities which added difficulty to its transit. That the obstruction was beyond the radial artery was sufficiently proved by the fulness of that vessel; that it was beyond the minute arteries of the retina and brain was shown by their often bursting from the pressure to which they were subjected by their contents. We had no choice but to go further and attribute the impediment to the capillary system, whether from change of blood *per se* or from vascular contraction engendered by it. With stoppage in front and accumulating systolic force behind, increase of transudation would seem to be inevitable. Whatever the nature of the hindrance in the capillaries, we might presume from the phenomena of inflammation that it was consistent with an increase of transudation from them.

In the later stage of renal dropsy the action of the heart and arteries had also to be reckoned with. As their hypertrophy increased the effusion tended to lessen. This was at first sight difficult to reconcile with the early increase of dropsy. But the arterial thickening could not fail to obstruct the access of blood and dam it back in the heart and large vessels, with the result of increased tension and increased cardiac hypertrophy. Now look for a moment at the left ventricle with its solid, thick wall and the comparative smallness of its cavity as yet undilated. The smaller the cavity in relation to the thickness of the wall the greater the rigidity of the chamber and its consequent expansile power. The suction thus exaggerated must tend to pump out the waterlogged tissues by drawing first upon the lungs, then upon the systemic veins and their tributaries. Later still, the hypertrophied ventricle began to stretch, and then lost, not only expansile power, but valvular adaptation. Dropsy reappeared or increased, and was now as much cardiac as renal. Mitral regurgitation ensued through the widened orifice, though the valves might be healthy, and a murmur was often heard which might mislead the unwary as to the origin of the disease: as a more striking consequence pulmonary apoplexy with hæmoptysis presented itself as a direct and simple issue of the cardiac changes of advanced renal disease.

On the evening of the same day the first meeting for this season of the Medical Society of London took place. Dr. Douglas Powell gave a short presidential address. Mr. Mansell Moullin then read a paper in which he advocated the treatment of compound fractures into joints by immersing the injured part in a bath of corrosive sublimate at the temperature of the body. If the accident were recent and the wound clean, the strength of the solution should be 1 in 10,000, with a few drops of hydrochloric acid added, and two hours' submersion night and morning would be sufficient. If, on the other hand, the injured part was foul, or some time had elapsed and inflammation had already set in, the bath should be continuous, night and day, for forty-eight hours, and the strength of the solution should be 1 in 1,000 for the first two. Over thirty primary cases of severe injury had been treated in this way with perfect success, except in two instances, in both of which the failure was traced distinctly to an escape of sewer-gas. Almost the same could be said of the secondary cases, but in one, in which a period of five days had been allowed to elapse, a secondary abscess formed (without a rigor or other sign of pyæmia) in the iliac fossa on the opposite side of the body. Professor Bahadhudji, of Bombay, read a paper on the "Treatment of Dysentery."

Almost all the societies have now commenced work for the winter. The Pathological Society commenced their labors on Tuesday evening last, the regular business being preceded by a short address from the President, Sir George M. Humphry. He expressed approval of the enlargement of the scope of the society. Solidism and Humoralism, he said, had ceased to attract, and we were now between the two, in the borderland of minute, almost imperceptible, chemical and microscopical changes. Hitherto we had regarded pathology as advanced physiology, and morbid processes as a modification of the processes of healthy nutrition; but we were now advancing into a region beyond the actual processes

of healthy and morbid nutrition, into the wide field of the causes of the morbid processes. The property of certain diseases to give immunity against themselves was replete with interest and seemed to have a wide range of influence. It had its illustration in one way in vaccination, and it was remarkable that this kind of illustration should so long have stood alone, though certainly that was less remarkable than that its protective power against small-pox should have been doubted by reasonable and observant persons, or that it should be supposed that so great a good should be conferred without any attendant evil. Was it in such immunity-giving property that the secret of the influence of counter-irritants lay? Some such effect (caused by absorption of the altered proteids in a blister) had been hinted at by Dr. Brunton.

WATER AS A LOCAL ANÆSTHETIC—ITS DISCOVERY AMERICAN AND NOT GERMAN.

To the Editor of the Medical Record.

Sir: For some time past an item has been going the rounds of the press, both medical and lay, in this country, to the effect that a German surgeon, Dr. C. L. Schleich, has recently shown, by experiments upon himself and his assistants, that water is a local anæsthetic, when injected hypodermatically. This first appeared, I believe, in the *Deutsche Medizinische Zeitung*, No. 66, 1891. The Medical Record, among other journals, a month or so ago briefly mentioned it.

I have waited since then, expecting as a matter of course that someone would come forward to correct the idea that this discovery is anything new; for many physicians besides myself must know that it is an old story.

In 1885 I called on Dr. William S. Halsted, then of this city, now Surgeon-in Chief at the Johns Hopkins Hospital in Baltimore. I was at that time making some investigations in regard to local anæsthetics, and Dr. Halsted was better informed than myself.

In the course of our conversation Dr. Halsted remarked that he had recently been using water by the hypodermic needle as an anæsthetic for small operations, and with success; that only the day previous he had employed this method in the removal of a small tumor from a patient living on the same block in which his office was situated; and that he had found that this plan succeeds best when the water is thrown into the skin, not beneath it; in other words, that the more superficial the incision is to be, the more satisfactory will be the anæsthesia by water.

I was much interested in this statement of Dr. Halsted's; and in order to satisfy my curiosity as to just how the water obtunded sensation, made a few experiments upon my own person. It occurred to me that possibly the anæsthesia might be mechanical only, and due to pressure, by the water, upon the sensory nerve-endings. In one of these experiments I tried to produce an equal or greater amount of pressure by another means, and then see whether sensation was abolished thereby. Dr. F. A. Manning, of this city, assisted me on this occasion. A hypodermic needle was attached to the tube leading from my compressed-air receiver, which had been pumped to a 40-pound pressure. This needle was now inserted beneath the skin of my left forearm, and the tap turned on slowly. The air distended the subcutaneous cellular spaces and then stretched the skin to tenseness and the production of very considerable increase in circumference of the limb. We continued until the crackling feel of subcutaneous emphysema could be noted, on pressure, from the fingers to and including the shoulder; and the skin of the forearm felt to me almost as tight as a drum-head.

The æsthesiometer was used both just before and upon concluding this experiment; and, briefly, it was shown that while some numbness was produced, the sensation was not enough abolished to permit of a cutting operation without pain; and that water probably has an analgesic property of its own.[1]

As an additional evidence that the idea of analgesia from subcutaneous use of water is nothing new, I quote the following passage from Bartholow's "Materia Medica," 5th edition, 1885, p. 690; subject, Aquapuncture: "It is a remarkable circumstance that aquapuncture has the power to relieve pain in a superficial nerve. So decided is this effect that there are physicians who hold that the curative effect of the hypodermatic injection of morphine is due, not to the morphine, but to the water!"

Very respectfully,

Robert H. M. Dawbarn, M.D.

AN ABUSE OF POSTAL PRIVILEGES.

To the Editor of the Medical Record.

Sir: In mailing the circulars of the Bellevue Hospital Medical College for 1891–92 from a list in the possession of Messrs. William Wood & Co., one was mailed to Dr. C. A. Dreis, 1401 Mitchell Avenue, St. Joseph, Mo., with a one cent stamp, as usual. This circular was returned "unclaimed." When sent to the Post-Office in New York, the wrapper was properly stamped and contained nothing but the circular. When returned an additional one-cent stamp was on the wrapper and both stamps had been cancelled. The wrapper when returned contained a pamphlet on "Nervous Prostration," one on "Leucorrhœa," and one on "Threatened Miscarriage," all issued by one and the same house in St. Louis, Mo. These advertising circulars, "For the Medical Profession Only," were put into our wrappers while the matter was in charge of the Post-Office Department. They added to the weight of the package so that another stamp was required, which was attached and cancelled. The College is put in the position of indorsing the proprietary remedies for nervous prostration, leucorrhœa, etc., to the extent of sending the circulars in its own wrappers. What sort of an offence this is under the postal laws I do not know, but it is the most outrageous example of effrontery on the part of proprietary medicine venders that has ever come to my notice.

Austin Flint, M.D., *Secretary*.

October 30, 1891.

THE CHLORIDE OF GOLD CURE FOR INEBRIETY.

To the Editor of the Medical Record.

Sir: I have received several requests to give the readers of the Record my views of the bichloride of gold excitement. As this subject has only a psychological interest the limits of a brief note will be sufficient.

Practically, the bichloride of gold is a therapeutic nihility. So far, the best authorities agree that any form of gold is inferior to iron as a medicine. Any physician can show that a combination of cocaine, strychnine, and atropia, or other similar drugs, used hypodermically, will effectually check the craze for spirits. As long as it is given two or three times a day, all forms of alcohol will be distasteful, and abandoned under all circumstances. This is simply chemical restraint, which is well understood in all the insane, inebriate, and private asylums of the country. The permanent cure or restoration of these complex insanity cases, in three or more weeks, by chemical restraint, is startling, to say the least.

The extraordinary confidence of permanent cure, and the almost enthusiastic delirium to make it known, by the persons who have taken this treatment, is not only startling, but unknown in the history of other diseases.

Psychologically, this unusual interest marks a distinct stage in the advance of every great truth. The statement that inebriety was a disease and curable, has passed the stage of denial and opposition, and come to the

[1] For further details, see my article on Surgical Emphysema, in Wood's Reference Handbook, vol. ii., p. 678.

second period of credulity. This is the time for specific remedies, and the opportunity for the quacks and camp-followers of science, who, recognizing the demand for help and the confusion of facts and theories, take advantage of the situation for the most selfish purposes.

By and by this period of credulity will be followed by a scientific era of organized fact, in which specifics and extravagant claims will disappear. The bichloride is only one of more than a dozen different remedies on the market, and advertised as specific cures of all forms of inebriety. All these remedies are sustained by innumerable certificates of clergymen, editors, and cured patients, and even physicians' names appear as references. Two facts seem to be very prominent in this bichloride movement. One, the intense interest of the public in any possible therapeutic measures that will check inebriety and relieve or cure the victim. The other, the dense ignorance and consequent credulity manifest for the remedy or method of treatment that by shrewd advertisement becomes most prominent.

The nature and value of alcohol and its effects on the body have, during the present year, been more widely discussed in medical circles than ever before. Political parties, societies, and churches have all manifested unusual interest in this topic. Public sentiment has passed beyond the realm of the exclusive use of moral remedies, and with childish expectancy is ready to welcome any mysterious medication that promises unusual and positive results. No matter what remedies are proposed, or theory advanced of their action, they are accepted, simply on the statements of non-experts and enthusiasts.

Thus one remedy follows another in regular succession, until the period of credulity and empiricism is replaced by one of scientific research. Inebriety is a complex insanity, involving borderland questions and ranges of causes that are unknown to the most advanced students of medicine and psychology. Exact theories and exact remedies are always reflections of the ignorance of the authors.

The same great principles of scientific truth obtain here as elsewhere. There are no "short cuts," no miracles, no discoveries that grow on mystery. Great facts and truths are never found except along great trunk lines of research, where they can be verified and confirmed by critical experience and study.

Yours,

T. D. CROTHERS, M.D.

HARTFORD, CONN., November 11th.

Navy News.

Official List of Changes in the Medical Corps of the United States Navy for the week ending November 7, 1891.

SIMONS, MANLY H., Surgeon. Ordered to the Mohican.

DUBOIS, FRANK, Medical Inspector. Ordered to the Philadelphia.

WOOLVERTON, T., Medical Inspector. Detached from the Philadelphia, and ordered before Retiring Board.

BLACKWOOD, N. J., Assistant Surgeon. Detached from the Newark, and ordered to Navy Yard, League Island, Pa.

BROWNELL, C. DEW., Assistant Surgeon. Detached from Navy Yard, League Island, Pa., and ordered to the Newark.

LEACH, PHILIP, Passed Assistant Surgeon. Detached from the Naval Academy, and ordered to the Monocacy.

PAGE, JOHN E., Assistant Surgeon. Detached from the Independence, and ordered to the Iroquois.

FIELD, JAMES G., Assistant Surgeon. Detached from Bureau of Medicine and Surgery, and placed on waiting orders.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 31, 1891.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	30	14
Scarlet fever	79	11
Cerebro-spinal meningitis	2	2
Measles	41	3
Diphtheria	113	41
Small-pox	0	0
Varicella	0	0
Pertussis	0	2
Erysipelas	1	0
Mumps	1	0
Rötheln	0	0

Action of Urea on the Vascular Walls.—Dr. Munk, several years ago, on perfusing blood to which urea was added through a surviving kidney, found that the addition of urea accelerated the blood stream, and increased the secretion from the kidneys. This result was also produced by sodic chloride, the sulphates and phosphates of the alkalies, creatin, sugar, creatinin, and other substances. The vaso-dilator action of the urea on the kidneys was not due to the action of the urea on the central nervous system, for it occurred in the excised and still living kidney. Cavazzani and Rebustello have made somewhat similar experiments by perfusing blood mixed with urea through several organs, but in all cases the organs or parts were left *in situ*. The fluid perfused was 1 part of bullock's blood mixed with 2 parts of normal saline solution (0.75 per cent. common salt). The animals employed were dogs, cats, and rabbits. The quantity of urea added to the blood varied from 0.5 per cent. to eight per cent. as a maximum. Urea possesses a marked vaso-dilator action not only on the blood-vessels of the kidney, but also on the vessels of the brain, liver, and musculo cutaneous vessels in the last case, as shown by its action on the blood-vessels of the hind limbs. Speaking generally, the vaso-dilator action of urea is directly proportional to the quantity per cent. of urea present in the blood. The minimum percentage of urea required to cause vaso-dilatation is for the kidneys 0.5 per cent., and for the other organs mentioned one per cent. In opposition to Munk, the authors have never observed a secretion of true urine during their experiments.—*The British Medical Journal.*

La Independencia Médica, an esteemed contemporary of Barcelona, celebrated its twenty-seventh anniversary on the first of October just passed. This journal is one of the most welcome of our Spanish exchanges, and we congratulate it upon its well-merited prosperity, and wish it *ad multos annos*.

Free Medical Attendance.—At the recent session of the German Socialist Congress, held in Erfurt, a new and revised platform was adopted, one plank of which demands "free medical assistance, including attendance at childbirth, free medicine, and free disposal of the dead." We do better than that in New York, for we not only give free medical assistance and free medicine, but also sometimes, if it happens to be an interesting case and several clinics are after it, a free ride to and from the dispensary. This is truly the home of the free.

The Influenza is still epidemic in several places in Russia, among others, Nijni-Novgorod, Warsaw, and Kiev.

The University of Vienna.—The number of medical students at the University of Vienna last summer was 2,427, and of these 348 were foreigners of various nationalities. The numbers have considerably fallen off as

compared with the previous winter, when there were 3,242 students in the medical department. In the summer semesters immediately preceding that of 1891, the numbers of medical students had been respectively 2,296, 3,185, 2,553, 3,105, etc. There has also been some diminution in the number of foreigners attending the school.

Rachitis is stated by Dr. Angel Conteras, in the *Boletin Médico de Puebla*, to be a very rare disease in Mexico.

A Case of Traumatic Tetanus Cured by the Antitoxine of Tetanus, is reported by Dr. Schwarz, in *La Riforma Medica* for October 15, 1891. The case was treated by Drs. Tizzoni and Cattani, and is the second one that has been cured by this antitoxine.

Doctors have the Right of Way.—An ordinance has recently gone into effect in Berlin which will give the right of way to carriages of physicians driving through crowded streets. In order to distinguish doctors' carriages from others the coachmen will wear white hats.

The Welz Prize.—At the meeting of the German Ophthalmological Society, held at Heidelberg, from September 14th to 16th, the Welz prize for the best paper published in *Von Graefe's Archiv für Ophthalmologie*, in the years 1887, 1888, and 1889, was awarded to Professor von Hippel, of Königsberg, for his essay entitled "A New Method of Cornea Transplantation," which was published in Bd. xxxiv., Abth. 1. This is the sixth time the prize has been awarded.—*British Medical Journal.*

The Doctors were Needlessly Scared.—The physicians of Bavaria did not approve of railroads, and on the occasion of the opening of the first railway in that country, according to the *Bulletin of Pharmacy*, the Bavarian Medical Faculty denounced the innovation as follows: "Conveyance by means of carriages propelled by steam ought to be prohibited in the interest of public health. For the rapid motion cannot fail to create a disease of the brain among the passengers, which may be classed as a species of *delirium furiosum*. Even if travellers are prepared to run the risk, the onlookers ought by all means to be protected. The mere sight of a passing train suffices to cause the same cerebral disorder. Wherefore the authorities should insist on having a palisading of thick boards, at least five feet high, placed on each side of the permanent way."

Getting Ready for the World's Fair.—The increase of typhoid fever in Chicago is beginning to attract attention. The cause is said to be the low water in Lake Michigan, and the exceeding foulness of the river. Efforts have been made to divert the current of the river from the lake, and pumps erected to convey the water off into an affluent of the Mississippi system; but the plant is deficient. When the waterway to Lockport has been completed some relief is expected. Meanwhile Chicago must move in the matter if she expects to avoid the unenviable notoriety that Philadelphia obtained from her Centennial typhoid epidemic.—*Times and Register.*

A Five-Thousand Dollar Prize for African Medical Exploration.—The King of the Belgians has just announced his intention to give a prize of a thousand pounds for the best work upon the following questions: First, to point out from a sanitary point of view the meteorological, hydrological, and geological conditions of the districts of equatorial Africa. Secondly, to deduce from the knowledge in our possession the principles of hygiene necessary to be observed in these districts, together with facts showing the best mode of living, forms of diet, and occupation, and the most expedient methods of clothing for the purpose of preserving health and strength. Thirdly, to indicate the symptomatology, etiology, and pathology of the diseases common to the districts in question, and to lay down the principles both of prophylactic and therapeutic treatment thereof, and to formulate suggestions to be followed in the choice and dose of drugs, as well as in the establishment of hospitals and sanatoria. The competitors for this prize are reminded that in their scientific researches, as in their practical conclusions, they will have to make them apply to Europeans in the various localities of the Congo basin. The competition is open to all comers. The works of those competing will have to be transmitted to the Minister of the Interior and Public Instructor at Brussels on or before January 1, 1897. Five years is by no means too much time for the execution of an undertaking of such magnitude as that, in return for which a thousand pounds is offered in compensation.—*Medical Press.*

An Attempt to Render Tobacco Harmless.—Smokers may be pleased to learn that Dr. Gautrelet, of Vinchy, claims to have discovered a method of rendering tobacco harmless to mouth, heart, and nerves, without detriment to its aroma. According to him, a piece of cotton wool steeped in a solution (five to ten per cent.) of pyrogallic acid, inserted in the pipe or cigar-holder, will neutralize any possible effects of the nicotine. In this way not only may the generally admitted evils of smoking be prevented, but cirrhosis of the liver, which in Dr. Gautrelet's experience is sometimes caused by tobacco, and such lighter penalties of over indulgence as headache and furring of the tongue, may be avoided. Citric acid, which was recommended by Vigier for the same purpose, has the serious disadvantage of spoiling the taste of the tobacco.—*Science.*

Cheap Certificates of Merit.—The *Medical Press* states that several German drug houses have lately been favored with the attentions of a gentleman from Paris, who offered, for a consideration, to supply them with certificates of awards from an "Exposition Industrielle" at Ajaccio, in Corsica, of which no one had heard in industrial circles, but a prospectus of which he enclosed. To obtain an award it was not necessary to send any goods to Corsica. One had only to forward 50f. for a diploma, 60f. for a diploma with medal, and 100f. for a diploma with "the order and the Corsican ribbon," whatever that may have been. Illustrations of these valuable marks of distinction are added to the prospectus.

Injection of the Blood of Negroes in Yellow Fever.—Various attempts have been made by Richet and Verneuil to confer immunity from tuberculosis upon human beings by injection of the blood of immune animals, or animals that they believed to be immune, such as dogs and goats. Following upon these lines, Dr. Bordier now proposes to transfuse the blood of indigenous negroes into unacclimated white persons going to the tropics, as a means of prophylaxis against yellow fever. We have not heard of the actual execution of this proposed measure.

The Consumption of Tobacco in France.—Last year French smokers consumed 4,600,000 francs worth of cigars, 10,000,000 of cigarettes, 29,000,000 of snuff, and 91,000,000 worth of pipe tobacco. The greatest snuff-takers are old peasant women and priests. Snuff is often allowed to Sisters of Charity, as it renders the nose insensible to the bad smells of slums and hospitals, and acts as a disinfectant of the air taken in by the nostrils. The greatest number of pipe-smokers are along the coast from Nantes to Calais. Fisherwomen as well as sailors use the pipe. The consumption of ladies' cigarettes rose from 101,900 francs to 800,000 francs last year, and the orders received at the tobacco manufactory promise a still further increase under this head. There is one anti-tobacco society in France.—*The Sun.*

The Discovery of Dr. Caius's Grave.—Mr. John B. Lock, of Cambridge, writes to the *British Medical Journal* that the vault containing the remains of Dr. Caius, the founder of the college bearing his name, was recently found during the course of some alterations which are being made in the college chapel. It is a square brick vault, covered by a thin arch of bricks, which rises to the level of the floor. It is 4 feet deep, 8 feet long, and 3

feet wide. It contains one skeleton, which had been buried in an open coffin, as there were no traces whatever of any lid. The sides of the coffin were fairly complete, but they had fallen away to the side of the grave. The bottom had perished, and as the coffin had been placed upon two large stones the bones had fallen away somewhat from their original position. The grave was again carefully closed, and a stone placed upon it with a short inscription.

Tokyo Medical Association.—The fourth annual meeting of this society was held in Tokyo on September 1, 2, and 3, 1891. The meeting was very successful, several hundred members being in attendance.

Errors in Diagnosis.—In an interesting and instructive paper, in a recent issue of the *British Medical Journal*, William Cadge, F.R.C.S., Consulting Surgeon to the Norfolk and Norwich Hospitals, remarks as follows: "Let me, however, advert briefly to one or two diseases which in my observation have been most frequently overlooked or mistaken; and I would give the first place to diabetes, a disease which manifests itself with so few objective symptoms and in such a variety of ways. Cataract, as we well know, is often the accompaniment of diabetes, and I have heard Sir W. Bowman say that he had in a vast number of cases recognized diabetes—before unsuspected—by the peculiar appearance of the opaque lens. The coexistence, too, of boils and carbuncles, and of gangrene of a toe or finger—or even of suppuration of a joint of a toe or finger—with diabetes is common and familiar enough; but I have seen quite a number of cases of so-called prostatic disease in old men, in which the frequent micturition depended not on the readily suspected hypertrophy of the gland, but simply on the fact that, having a large quantity of urine to discharge, the bladder required frequent relief; and it is well to remember that this large quantity of urine and frequent micturition, though commonly due to ordinary diabetes, is occasionally the effect of diabetes insipidus. So, too, the coexistence of diabetes and lithic acid gravel and stone is not uncommon, and should be borne in mind, for the combination is formidable, and may prevent the cure of the otherwise curable stone. The mention of stone leads to the remark that, next to diabetes, the presence of stone in the bladder is perhaps most frequently either overlooked or undetected. There is no surgeon living—no matter how great his experience and his manipulative skill may be—who does not occasionally fail to detect a stone that exists in the bladder. I plead guilty to this myself, for I have had it brought home to me, and have felt not a little chagrin and self reproach at my shortcoming I am not going to describe the various methods of sounding for stone, but I wish to allude to one source of mistake only, which I have met with over and over again. I can best illustrate it by a case. A London hospital surgeon who was spending his holiday on the coast near Cromer, met with a sturdy old fisherman who had all the symptoms of stone. He induced the man to go to his London hospital, but he was surprised that, when there, no stone could be detected; he examined again and again, and called in one or more of his colleagues, and eventually sent the patient home with the opinion—afterward expressed to me—that malignant disease of the prostate was probably the cause of his symptoms. Yet this man had a stone which was successfully removed by lithotomy in the Norwich Hospital, and the explanation of failure to find it I believe was this: The patient was a tall, fat man, aged seventy-two, with an enlarged prostate, and the bladder was very deeply placed and distant; an ordinary sound would go to its usual extent, and could be partially rotated, but I soon found that it required considerable further introduction, and even to push back the flexible part of the urethra on the sound, in order to reach the bladder; but when it was reached the stone could not be missed, but I have no doubt that my London friend had never passed the sound fully into the bladder, but had only examined the deep prostatic sulcus, and the limited movement of the sound he probably attributed to a contracted bladder."

A Point for the Maternal Impressionists.—Under the head of "a curious coincidence," Mr. R. J. Leeper relates, in the *British Medical Journal* of September 19, 1891, that on August 5th last, he was called to attend a pregnant woman, who had some days before sustained a fright by seeing four deformed children (all of one parent, and all afflicted with "talipes varus"). When he arrived he found that she had just been delivered of male twins (seven months), and on examination of them he found both to be deformed from double "talipes varus." The mother had always been very delicate and nervous.

The Influence upon the Child of Medicaments Administered to a Nursing Mother.—Dr. Schling has made a series of observations upon children, to the mothers of whom various drugs were administered. If the infant was not put to the breast sooner than an hour after the administration to the mother of from thirty to forty five grains of sodium salicylate, the salicylate was found in the urine of the infant. At the expiration of twenty-four hours not a trace could be found. If the infant was put to the breast too soon after the administration of the drug, not even a trace could be found. The elimination of the medicament took place simultaneously in both mother and infant. Similar results were obtained with potassium iodide. In the infant the elimination lasted for seventy two hours; in the mother, for forty-four hours. At the end of twenty-four hours the mother's milk still contained potassium iodide. When potassium ferrocyanide was administered the reaction was evident in the maternal urine, but no trace could be found in the fœtal urine. When iodoform was for a considerable time employed by topical application to vaginal and vulvar wounds in women in childbed, iodine was, as a rule, found in the milk and maternal urine, but not constantly in the urine of the fœtus. The transmission of mercury to a nursing child through the milk is slight and may be irregular. The influence of the nourishment of the mother, that is the food ingested, appears to be *nil*. Nurses may with impunity be permitted to partake of acids (lemon, vinegar, etc.). Of narcotics, the ingestion of the tincture of opium, in doses of from twenty to twenty-five drops, has in some instances been followed by prolonged sleep on the part of the infant, while in others neither prolonged sleep nor constipation was observed. After the administration of morphine hydrochlorate, in doses of one eighth, one sixth, one-fourth, and one third of a grain, nothing in particular was noted in the child. Chloral, in doses of from fifteen to forty-five grains, brought about sleep of moderate duration in the case of the mother, without any action upon a strong and vigorous infant. When atropine sulphate was administered in medicinal doses subcutaneously to the mother, dilatation of the pupil was observed in the infant, disappearing in twenty-four hours. In a large majority of cases the milk of a woman with fever has no influence upon her infant. Except in rare instances of grave illness in the mother, with a persistent temperature of 104° F., the infant does not present the symptoms of the mother. In a case of mammitis the passage of micrococci from the breast of the mother to the digestive apparatus of the infant has been observed. —*Medical News*, October 24, 1891.

Tracheotomy on a Dog.—Dr. Charles H. Cockey, of Baltimore, recently saved the life of his little Scotch terrier pup, eight weeks old, which was apparently dead from strangulation by a piece of meat, by means of tracheotomy.

The Use of Cocaine.—The use of cocaine in the urethra is attended with more risk than when applied to any other part of the body. It should be positively forbidden in the recently cut or denuded urethra.

A CONTRIBUTION TO THE PATHOLOGY OF HÆMOPHILIA, ESPECIALLY IN REGARD TO ITS NEUROTIC ASPECTS, WITH THE PRESENTATION OF SEVERAL CASES IN ONE FAMILY.

BY ALLAN McLANE HAMILTON, M.D.,

NEW YORK.

IN all the contributions to the literature of this curious affection, which seems to be regarded more from its clinical than from any other stand-point, insufficient attention has been paid, I think, to the development and causation of certain symptoms, namely, the joint affections, and those which are purely cerebral in character. In fact, it would appear that the latter have been generally looked upon only as unimportant features of the affection. Of Grandidier's[1] large number of cases there seem to be very few that are carefully considered so far as their neurotic aspect is concerned, and even in a contribution so recent as Osler's[2] article, there is no mention of nervous disorder except a brief reference to the two cases reported by Buel.[3] Some of the foreign writers, however, speak of headache, mental disorder, epilepsy, and other indications of cerebral mischief, especially in those cases in which there has been joint involvement.

In three cases reported by Grandidier epileptic convulsions accompanied the disorder, and in a case presented by Brier, hemorrhages were preceded by epileptic attacks. In Cousin's case, which ended in death, there was epilepsy, the attacks being followed by various kinds of cerebral disturbances and some permanent mental degeneration. This boy had a second attack, six months after the first, which was fatal, the autopsy disclosing fresh blood clots at the base of the brain, and old cysts elsewhere. In Otte's case epilepsy appeared in the thirteenth year, and attacks were occasionally followed by maniacal outbursts. It was observed in this subject that no spots of discoloration appeared upon the surface when the patient was injured during an epileptic seizure

I was first consulted, about four years ago, by Mrs. M——, of Newark, N. J., in regard to her little son, then about nine years of age, who presented a well-marked history of hæmophilia, and to my surprise I found that several members of her immediate family were afflicted in the same way. Careful study of these cases, frequent inspection, and information given through the kindness of Dr. Wrightson, of Newark, who had attended them and who came to my office upon one occasion, has put me in possession of the following facts: Mrs. M——, the mother, is a native of Bohemia, is of good health, and knows of no bleeders in her family—brothers and sisters both having families of children, boys and girls, who have never given any evidences of hæmophilia. Being Jews, an early opportunity for the manifestation of the disease occurred at the ritual of circumcision. In these families, so far as she knows, there is no history of rheumatism or nervous disease.

Personal History.—Mother of the children has always menstruated profusely, the function lasting a week, but the flow has never been alarming; loss of blood during placental period of confinement profuse, but not serious; she was only once attacked with alarming hemorrhages, and that was on the ninth day of the first confinement, upon the day of circumcision, when she was rather nervous; and feeling as if she were flowing, she went aside to investigate the matter, when blood began to flow freely. She called for assistance, but fainted before anyone came. Later on, it was discovered that the child had been bleeding since the ceremony, but of this she was ignorant. She was so much frightened at its appearance when it was brought to her that she began to flow most alarmingly for some time. She has never had any ecchymoses

[3] Trans. of the Medico-Physical Society of New York, vol. i., 1817.

or bled unduly after injuries, nor has she had any serious bleedings in her subsequent confinements. The father, a native of Westphalia, is in good health, has never had any hemorrhages, nor have any of his family; there is neither history of rheumatism nor nervous disease in his case.

Case I.—Frank M——, born November 1, 1875; bled twenty-four hours after circumcision, until nearly exsanguinated, and it was seven weeks before they dared to handle him. No dropping of umbilical cord (mother says cords of all her children were thick and did not separate for from ten to twelve days). No further sign of hemorrhage until he began to walk and bruise and bump himself, when very large ecchymoses always appeared and were caused if he were handled with any rudeness. When five years of age he met with his first accident, from which he almost bled to death, the edge of his foot being lightly stepped upon by a horse, yet not enough to frighten him. The nail of the great toe was somewhat loosened, but there was no hemorrhage. During the night the mother awoke and found the child in bed covered with blood. The flow lasted, on and off, for seven weeks, the blood finally seeming to ooze through some granulations at the corner of the nail. When the bleeding ceased convalescence was quite rapid, but the nail was never properly reformed. With the loss of each tooth hemorrhage occurred which lasted from several days to a week; and with some teeth the hemorrhage was very alarming, so that they were never drawn. No bleeding followed vaccination. He had epistaxis but once, and that was not serious. Joint symptoms first appeared when the boy was ten years of age, and involved the knees and elbows, mostly, however, the knees, which now are larger than normal, but there is no marked embarrassment of motion. The first phalanx of the third finger of the right hand is always the seat of swelling; the pain in joints has always been very severe and quite out of proportion to the swelling. The pain is hardly like that of ordinary rheumatism, but for the most part consists of lancinating and darting pains which are not confined to the joints, but in lower extremities seem to follow the course of the sciatic and other nerves. Dr. Wilke, who saw the case at my request, found that one of the brothers, who has an enormous swelling of the joint, has little or no pain, and he who always had least swelling suffered the most severe pain after the joint symptoms had existed about two years, following a most severe attack of his knee trouble, that is, swelling and pain in the knee. The pain suddenly left the knee, when the lad complained of most excruciating frontal headache, lasting about nine days, during which time he did not seem to be himself, and asked to be assisted to empty his bladder and rectum, but did not ask for food, though when it was brought to him he ate it voraciously, not at all in his usual manner. When the attack passed off he seemed to remember little or nothing about it, sitting up suddenly in bed, asking what day and date it was. The attacks, though, did not cease, and probably there would be an interval of an hour or so with less pain, then return of pain, then a longer interval, then pain again, until it ceased. During the attack he desired to be in the dark and could not bear any noise, not allowing his mother to leave his side. The shortest interval between attacks was a week, the longest six months; he now has not had any since June, 1890 (December 11, 1890). During the headache he had severe tachycardia, of which he complained, and this was noticed by his mother. I saw him during two of these periods, when his mental condition was one of exceeding interest. His facies indicated very great suffering, but at the same time there was a suspicion of hysteria, and his behavior clearly showed such a state. The boy now looks quite rosy and well, is manly in his sports; his heart's action is somewhat forcible, and his pulse beats 120.[1]

[1] October 4, 1891. Frank M—— has been seen twice since this article was written, and upon the last occasion presented a marked hebetude and dulness.

Case II.—Julius M——, born August 4, 1887; no hemorrhage after circumcision, which was performed when the child was two weeks old; he never bled or had any ecchymoses, and died when eight months of age, of pneumonia.

Case III.—Solomon M——, born April 25, 1879; circumcised on the ninth day, with occasional bleeding for three weeks, and he was seven weeks old before they dared to handle him without great care; pains in the joints when five or six years of age, with severe swellings. Pains are much less than Frank's, but the swelling is greater. When he was nine years of age he struck his head when driving into a barn, but there was no rupture of the skin and no visible hemorrhage; but an immense hæmatoma formed, hanging over a great part of the face, and it was four months before this disappeared. He is a bright-looking lad, rather thin, but not pallid; pulse, 104, impulse slightly accentuated.

Case IV.—Jacob M——, born 1881; was circumcised like the other lads, he has always had large ecchymoses on receipt of injury, no matter how trifling. When he was three years of age he fell against an iron safe, hitting his head over the frontal bone; the hemorrhage lasted for several days, subsiding at times; it was severe enough at the time to almost kill him, and it took the wound two months to heal, which it did after discharging a splinter of bone. He now has a depressed scar on the temple. Upon another occasion he almost lost his life from bleeding of lips, which he bit in falling; a large hæmatoma formed; the hemorrhage from the mouth lasted one week. He, like his next elder brother, is rather frail-looking, but not pallid. He first had his pains and joint symptoms when five years of age, has more swelling about the knees than Solomon, and less pain than he or his eldest brother have had, the latter of whom always had most severe pain and less swelling. This lad, J——, as his mother says, is "liable to puff up over night." His knees are somewhat larger and his gait is a little affected. His pulse is 112, and he also has some accentuation of impulse.

Case V.—Leo M——, born 1883; not circumcised; has been most prone to ecchymoses and severe, but comparatively painless, swellings. He has never had any hemorrhages except when teeth fell out, and these were slighter than those of any of his brothers. The most trifling injury produces large ecchymoses, and he has most frequent and very large swellings of right knee, which never regains its normal shape, causing him to limp. His mother says he falls much, and that swelling follows his falls. At present his knee is swelling, he having had a fall several days ago. The knee measures sixteen inches in circumference, the sound one, twelve; the skin is shiny and drawn, and feels like rather firm œdema, but is loosening around the edges above the swelling. About two inches above the upper border is a black and blue spot extending upward about three inches and is two inches wide in front of the thigh. His temperature is 102° F.; pulse, 140. The little fellow is very fat, abnormally so in fact, and has loose, flabby tissues.

Case VI.—William M——, born 1887; was not circumcised and has never bled seriously; he is only prone to ecchymoses, has not lost any teeth yet, nor has he had joint symptoms. His pulse could not be counted, as he is very restless, but slight irregularity in heart's action was detected. At visit of Dr. Wilke he pricked himself with a pin, and the little puncture, which could not be discovered, bled about an hour, so that the fingers and hand were besmeared with blood, no matter how often it was wiped away.

Case VII.—Infant, never circumcised, born 1888; has never had any ecchymoses on injury or given any indications of being a bleeder; seems to be perfectly well in all respects.

The blood which flows from these children clots firmly, but after the hemorrhage has lasted some time the coagulation is diminished.

The bleeders in this family at times manifest a certain amount of mental distress, headache and excitement, the most marked example, however, being that of Frank M—— (Case I.).

It will be seen that five of these children are bleeders, and that joint defects of greater or less gravity were present in each case.

Case VIII.—in the year 1885 I was consulted by Dr. D. B. Delavan, of this city, in regard to a lady, aged about forty, who suffered from the most intense headaches of an anæmic character, which I traced to certain drains upon the vascular system. These had lasted for many years, in fact, from the commencement of menstruation, and she had always had a much more profuse hemorrhage than was consistent with a normal exercise of function. No local cause had ever been found for this menorrhagia, and it had resisted the best directed efforts at control. The patient was of good stock, without any hereditary history whatever, except the transmission of an active nervous temperament and a poor physical make up. It was quite certain that there were no bleeders who were known. The first indication of hemorrage was when the patient was about seven years of age, when frequent bleedings from the gums occurred when studying in school. When ten years of age she suffered from a dysentery which was very intractable. At sixteen she was prostrated by typhoid fever, when epistaxis was alarming; but the abdominal symptoms were not marked; during convalescence spots of ecchymosis were produced by the slightest contact. A few days after this, her teeth needing filling, a dentist was called and by some accident let an instrument slip, which entered the gum, there being a resulting hemorrhage which very nearly killed the patient before it was stopped. After that year she was very subject to sore throat, which often ended in constant bleeding from the fauces and gums, and bleeding from these parts was very frequent and lasting. This constant drain resulted in a very great enfeeblement of the general system, so that the patient was very easily fatigued, emotional, and nervous, and suffered from the headaches I have described. When she was seventeen she began to have "rheumatic" pains and enlargement of both knee joints, which still exist, though they do not compare proportionately with the same condition of affairs in the M—— children. She has periods of very great nervous excitement, quite hysterical in character, which alternate with very great depression and despondency, and has had at least one convulsive attack. In August, 1887, she had another accident in the dentist's chair—three loose teeth were removed, but when a sound eye tooth was pulled there was some slight fracturing of the alveolar process with very profuse hemorrhage, which was restrained with great difficulty. This loss of blood, which was attended by faintness, great sense of constriction in chest, swelling of the feet and legs, was followed by an unusually severe attack of knee pain; "her feet were purple, and would seem to blister and then bleed on the slightest provocation." For the past year she has had constant diffused head pain, and some photophobia. She is very susceptible to iron and rapidly improved under the use of the albuminate, while other preparations seemed to produce gastritis, her digestion being very much disordered.

The foreign cases in which neurotic and joint disturbances complicated hæmophilia are numerous, although there seems to be a disposition to regard the latter as gouty, or purely rheumatic. Immermann has observed all grades of joint affections, from inflammatory arthralgia to copious synovial effusions, and he considers the attacks to be rheumatic, because they appear during cold, damp weather, and have no relation in point of time with bleeding; and upon the fact that the effusion is mostly serous, and that the subsidence of pain and local disturbance is more in consonance with the explanation of ordinary rheumatic causation than anything else. He also holds that the rheumatism outlasts the tendency to hemorrhage. In answer to this, it is quite possible to assume, however that when the mechanical violence has been done the pain and swelling may result from the new products.

Grandidier and Hyde-Salter believe the affection to be closely allied to the rheumatic disposition. Grandidier has collected 31 cases, which were reported between 1863 and 1872. Of these 22 show enlargement of the joints, and in many such serious symptoms as the hemorrhage itself. In some of these there was resulting anchylosis and various permanent deformities. Three cases show anchylosis of the hip- and knee joint; 4, anchylosis in the hip-joint alone; 5, of the knee joint alone; 1, of the shoulder; and 1, of the elbow. So far as the history could be ascertained, injury did not appear to be the cause of these affections, but at first the information as to this point is by no means clear. The contents of the swelling was generally serous, at times blood was found, and sometimes clots. In cases reported by Camman, Stroemeyer, Reinert, Assmann, hemorrhage in which the joint was found to be the seat of the swelling, as was also the case in an example reported by Du Bois. In some of these cases the joint disturbance appeared in the fall or spring, when the weather was cold and damp, and the pain grew worse always at night. In others, the pains appeared in joints that were not the seat of swelling. It would seem, however, that "rheumatism" was not of the ordinary nature, for the additional fact that heart complications were observed but twice.

In some of my cases, and as the result of my examination of continental examples, I am impressed most strongly with the idea that the swelling of the joints and the painful symptoms are not due to rheumatism, and there are no accompanying indications, either in the urine or in the history of the case, that allow me to adopt this explanation as final and conclusive, despite many assertions to the contrary.

A careful study of the children of the M—— family convinces me that in no respect is the joint affection a distinctly rheumatic one, that is, so far as it is due to any uric acid causation. I am inclined to think that its development is dependent upon injury of the deep parts and the rupture of vessels, and consequent hemorrhage into the tissues; and with these children, as well as many of the foreign cases, there was rarely any substantial retrogression or change, but it would appear as if the enlargement was due to plastic deposit left after hemorrhage rather than to the effects of an ordinary arthritis. In these, and other cases, fresh attacks of pain and ecchymosis always followed blows where sometimes very inconsiderable force was applied, and the resultant effect of such violence was in direct proportion to the force. I have repeatedly closely examined the joints of these children, and have nearly always discovered very decided appearances of ecchymosis; and within a few days I have found in one of them (Jacob M——) that a painful swelling of the metacarpo-phalangeal joint of the thumb was the seat of a diffused discoloration which varied in depth. It is quite proper, I think, to compare the pathological process that takes place in these examples with that known to exist in hemorrhagic pachymeningitis, where successive hemorrhages result in increase of tissue, and such a condition of affairs in any of the joints would account for the very great enlargement and the pain; so it is not unlikely that in the case of Frank M——, or, in fact, any other case where there is very much headache or epilepsy, or where cerebral disturbances are associated with the disease, that the actual condition of meningeal thickening has followed hemorrhages due to blows upon the head, or falls.

20 East Twenty-ninth Street, October 4, 1891.

Strychnine as a Heart Stimulant.—Strychnine is regarded as the best heart stimulant in weakness of the heart. The heart beat becomes strong, the small arteries contract, and the blood-pressure increases.

A FLAP-SPLITTING OPERATION FOR THE RADICAL CURE OF INGUINAL HERNIA.[1]

By B. E. HADRA, M.D.,

GALVESTON, TEX.

THE actual results of the present operations for the radical cure of hernia are not satisfactory, statistics showing a great percentage of relapses. This is my excuse for offering a new operation for inguinal hernia.

We find in the modern, so-called direct, operation three points aimed at: 1. Obliterating or removing the sac. 2. Closure or narrowing of the openings and of the canal itself. 3. Restitution of the normal obliquity of the canal.

In regard to the first indication, I think that too much stress has been laid upon the instrumentality of the peritoneal sac to produce and to maintain the hernia. Its rôle is more passive than active; and even if the theory that the presence of the peritoneal pouch is the primary fault be true, nevertheless the width of the internal ring seems to be the more important factor surgically. If this latter is narrow enough, it will not allow the gut to pass into the sac within the canal, and finally the sac will shrink and atrophy. While this is evident in acquired hernia, it seems to be the case also in the congenital form. The vaginal process of the peritoneum is, as a matter of course, present in every individual, and it is open at least in early fœtal life, and in most instances at birth. Consequently inguinal hernia would be the rule. On the other hand, we know that an abnormally wide internal ring is a frequent and hereditary fault of development, and it seems therefore more rational to look on this latter defect as the primary cause of hernia. The atrophy and the consequent closure of the peritoneal process is due to the compression exercised by the internal ring. If this latter be too wide, it will fail to do its duty. This seems to me the best explanation of the mutual relation. But whichever is right, it is obvious that a permanent closure of the entrance to the canal by operation must prevent the intestine from getting into the sac, provided, of course, that the latter could be emptied of the former before the closing.

However, as undoubtedly a pouch with a large opening is an invitation to the intestine to enter, its occlusion may be of great service as an addition to the more important act of obstructing the internal ring.

There are three ways of treating the sac: 1. To return it into the abdominal cavity, which will be the best with small, merely peritoneal pouches, when they are free or easily detached. 2. To contract the neck of the sac. 3. To remove it.

Constriction is made by carrying a ligature by a blunt instrument around the sac. If the adhesions be too firm, a needle may be used, having proper regard for the cord. In congenital hernia this latter has to be well separated first, and it should be kept in mind that its structures are sometimes divided into two or more portions. Another method is to draw the sac out sideways where it is free from the cord, and to tie it laterally. If the ligature can be applied without opening the sac, the operation remains extra-peritoneal; yet an incision has to be made in strangulated cases; or when there are adhesions within the sac; or when we do not feel certain of having emptied it thoroughly of its contents; or finally, when omentum has to be resected.

Removal of the sac means cutting away its pouchy part after detaching it from the adjacent tissues. Some operators cut away all below the ligature. The advantage of such devices hardly pays for the additional danger and trouble. Necessarily a large wound-cavity is produced. A good constriction excludes perfectly the lower part, and it will then gradually shrink and become solid. It would be only from cosmetic considerations that large pouches, reaching into the scrotum, would be better done away with, but time greatly remedies the evil by atrophy. On the other hand, the firmly adherent and solid mass of the sac left behind, may serve as a plug to the canal, and as a kind of a bracket for the upper tied-off portion. But it is different when the sac is used to form an artificial occlusion in the canal or in front of the internal ring. Here there is some use made of it, compensating to some extent for the detaching and cutting manipulations. Still, I think, even such methods are of little real value. The width of the canal by itself is, as already said, of secondary importance, and a barrier, as formed by Mr. Macewen's plug, is not in any way superior in its defensive effect to a firm closure of the internal ring, if this is done thoroughly. My conclusions, then, in regard to the treatment of the sac are, that its obliteration or removal is not the main point in curing the hernia, but that under certain circumstances it will offer additional safety. But this occlusion has to be made on a level with the internal ring, or above it, as in McBurney's operation. It is evident that if a pervious part of the sac be preserved within the canal the complete hernia will be merely turned into an incomplete one, provided, of course, that no other precautions to prevent the intestine from entering be taken. There is only one good excuse for meddling with the sac, and that is to restore the normal shape and surface of the peritoneal cavity, and not to allow any new pouching of it opposite to the internal ring.

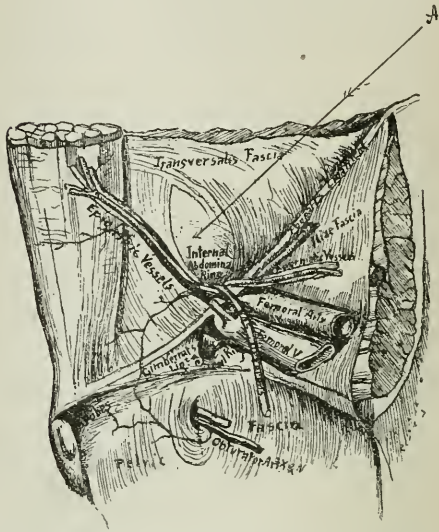

FIG. 1.—(Taken from Gray's Anatomy.) The Relations of the Femoral and Internal Abdominal Rings; seen from within the Abdomen. Right side. A, The oval-shaped fossa.

Now, as to the closing of the openings and the inguinal canal. The great majority of operations aim only at the outer ring, taking in perhaps the more external portion of the canal. By such methods nothing is gained, but again the complete hernia is made incomplete. The outer opening is simply closed, while the gut is freely admitted to the canal above it. Even if the sac were tied off higher up, the abnormal width of the entrance of the canal would, at any favorable occasion, allow a new invasion of peritoneum, omentum, and intestine. A more resistant protection against a relapse will be the closure, or rather the narrowing, of the whole extent of the canal, as some new devices demand. But evidently, the most sensible and most natural safeguard will be procured by the closure of the internal ring, so as not to allow the beginning of an intrusion into the canal. The question only is: What constitutes the internal ring? If only the narrow slit through which the cord passes is considered as such, I insist that the work cannot be done securely and reliably.

As you can see on the cadaver or on every anatomi-

[1] Read before the Austin District Medical Association, June, 1891.

cal plate, the internal ring begins with an oval-shaped depression in the abdominal wall, lined and surrounded by very strong fibres of the transversalis fascia (Fig 1, A). This fossa has a diameter of about two inches. It extends upward and somewhat inward from the real opening. It corresponds in many individuals to an elevation on the outside of the abdomen, which can best be seen during an attempt at cough. If the whole inguinal canal be compared to a funnel, then this depression represents the cone, while the canal proper is the tubular portion. Now, this conical groove has to be cared for in the operation before all other parts, because it has to withstand the force of the abdominal pressure as the first and the strongest obstacle. Under untoward circumstances the tissues of this fossa become yielding and attenuated by the constant aggression of the intestines. The latter work themselves in, as it were, pushing out the peritoneum to fit the depression. By and by the ring gives way, the cup becomes flatter and pouch-like, and the hernia burrows more and more in, and finally lifts up the anterior wall of the canal, gradually progressing into and finally out of it. Thus the hernia begins even before it enters the canal, not because there is a preformed pouch of the peritoneum (which may however happen occasionally), but because the fossa in the abdominal wall is not normally shaped, or not normally resistant, which in most cases will be an inherited defect. The peritoneum, of course, cannot help following all the changes in the abdominal wall. (I have a slight suspicion that the pre-peritoneal hernia, on which lately so much has been said, is nothing but a common hernia in a very pouchy fossa, and just in the act of sending forward a process into the canal.)

If that all be so, then the necessity of mending the condition of the fossa of the internal ring is obvious. It is, in my opinion, the key to a reliable permanent cure.

A few words now about the obliquity of the canal. Normally it is so inclined as to be rather compressed by the intra-abdominal wave; but the straighter it becomes in the postero-anterior direction, the more easily it will be entered by the peritoneal pouch. It is therefore very desirable to have the canal's normal obliquity restored.

Summing up: The foremost requirement for a permanent cure is the reparation of the abdominal ring in its entirety. Of additional service are the restoration of the normal obliquity and of the normal calibre of the canal, and the obliteration of the sac. In my opinion the first act will by itself be sufficient.

I will now proceed to investigate how these indications are best met. It is not necessary to describe fully and criticise the methods of closing the outer ring alone. They are, from all that has been said, perfectly inadequate to the task, and it is enough to state that the two pillars have been brought together by sutures; also that the conjoined tendon has been stitched over to the middle of Poupart's ligament; that another surgeon advised bringing the pyramidal muscle over the outer opening, and so on; not to mention older devices of invagination, subcutaneous sutures, etc. In order to contract the canal in its whole extent, the main means is the formation of cicatricial tissue, either to fill it, or to surround the flaccid walls with rigid cicatricial rings. The first is most energetically sought by a massive longitudinal cicatrix in McBurney's operation, the latter by carrying sutures around the canal (of course excluding the cord) by different methods. Marcy, for instance, uses his particular tendon suture, Schede takes silver wire and leaves it in. Others apply simple catgut or silk stitches, firmly bringing together the two halves of the split canal. Evidently, however, the dependency solely upon cicatricial tissue is a very weak point, and makes all such methods unreliable. In all our pathological experience cicatricial tissue has the tendency to atrophy, to become absorbed, and relapses are therefore nothing that we ought to wonder at. To avoid such mishaps Riesel removes a longitudinal strip from the anterior wall of the canal before bringing the wound together, thus uniting muscular tissues after the narrowing—obviously a great improvement. Finally I may mention the attempt to form a new canal, as in Bassini's operation.

Now, all these methods are concededly successful in a great many instances, statistics showing about fifty to seventy per cent. of permanent cures. But even such results should not satisfy us. From what has been said, there are two mistakes made, to avoid which is necessary to success. One is that the cone of the interior ring is not included in the operations, and the second mistake is that the improvement of the structures to be made tenser and more resistant is not of a permanent nature. To the first point I insist that the usual extent of slitting of the canal, even through the internal opening, is insufficient. The incision is usually of the length of one and a half to two inches. But in order to reach or, even better, to run through the fossa, it has to be made at least three inches long. The incision has to be made obliquely, about parallel to Poupart's ligament, so as to restore the obliquity of the canal. The upper end may, perhaps, be bent inward, to meet the fossa better. The incision then will have the shape of either a light bow or of an angle with a long and a short shank. Still a linear incision will, for simplicity's sake, most likely do, as from its termination the adjoining parts can be reached to any extent wished.

The second improvement has to be applied to the method of tightening and strengthening the involved parts. Cicatricial constrictions or plugs are not safe. We will best use muscular union. And I think that this is best obtained by a flap-splitting operation modelled after Lawson Tait's method, an operation which has been successfully performed in ventral hernia by Saenger, of Leipzig (induced, as he states himself, by Tait's remarks), and in a similar case by Edebohls, of New York. It is true that I have to show only one case of the operation adapted to inguinal hernia; also, that the time since the operation is too short to prove its efficacy. But it is to request you to try my propositions and to put them to test, that I read this paper to you.

Leaving out the minutiæ, not differing from such in other methods, the operation consists of the following acts: 1. Skin incision, extending from the outer ring, parallel to Poupart's ligament, sufficiently to get a good access to the field of operation, say four to six inches long. 2. Exposing the external ring and the abdominal fascia over the canal, freeing them with blunt instruments and finger. 3. Detaching the contents of the canal from its anterior wall. This has to be done with proper care. The finger has to be inserted high up and the peritoneum detached from the transversalis fascia to the full extent of the internal ring, the fossa included. 4. Slitting the abdominal wall with knife or scissors on the left index-finger, in the long axis of a supposed normally situated inguinal canal, for fully three inches, curving the incision somewhat inward in its upper third. 5. Attending to sac and testicle; either simply returning the contents of the former into the abdominal cavity, or ligating the sac above the level of the internal aperture, with or without detachment from the surrounding tissues, or removing the sac—as the case may be, or the operator chooses. A diseased or undeveloped testicle, if in the way, is best removed. 6. Carrying a fine, long bladed knife flatly around the lips of the wound, so as to split the adjoining abdominal wall into two layers for the distance of one-half to one inch. The more lax the parts and the larger the calibre of the rings and the canal, the more the splitting has to extend toward the periphery. It is not difficult to satisfy oneself about the situation of the fossa; of course, the more thoroughly this is included in the splitting, the more successful the operation will be. It is advisable to have an assistant steady the lip of the wound with two tenacula while it is split. The diagram (Fig. 2) shows the method fully. The line *a*, *a*, represents the distance to which the splitting of the tissues is

carried; *c*, the line of incision. 7. Carrying a continuous suture through both raw surfaces in as many longitudinal rows as may be necessary to bring the surfaces well into contact. Catgut may be used, as I have done in my case, but perhaps silk will be more reliable. The sutures be-

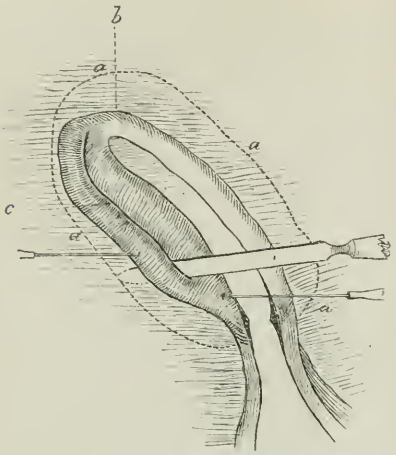

FIG. 2.—Operation on Left Side. Splitting nearly done through the right lip of the wound.

come buried. The black dots in Fig. 3 show the points of entrance of the needle. The numbers 1, 2, 3 indicate the lines of three rows of sutures. In some cases two may do, in others perhaps more will be desirable. It is important to have a good apposition, especially of the middle line, so that no interspaces and caverns be left below. The first row, commencing in the upper angle, has to take in the transversalis fascia. Bringing the latter up by a fine tenaculum will assist greatly. 8. The tendinous

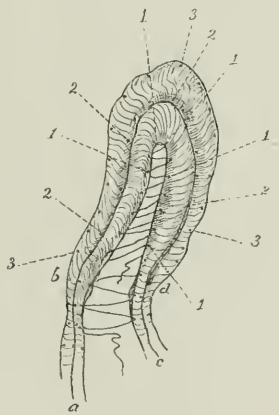

FIG. 3.—Operation on Right Side. Splitting done all around; first row of uninterrupted suture inserted.

pillars below and to the sides of the external ring (Fig. 3, *a b* and *c d*) may now also be split and sewn together in the same manner as the canal. Thereby an additional closure of the external ring is obtained. 9. Finally the wound is closed in the usual way, with or without drainage. I think the best dressing is a layer of cotton fastened to the skin by iodoformed collodion. It does away with all kinds of bandages, which are more or less of a nuisance. Still, if they should be preferred, a good cotton-padding and a spica are all that is needed to complete the dressing.

The proposed operation is much simpler than it appears from the description. It can be performed in thirty minutes without any undue haste. If the sac is not opened, it remains entirely extra-peritoneal, the whole procedure involving solely the abdominal wall. But even if the sac should be incised or resected, the surgical danger is in no way greater than in all other direct methods. Further advantages are, that no tissue is sacrificed; that one can narrow the parts to any extent desired; that the opposing raw surfaces are large, muscular planes; that the line of union will not cicatrize; that a sort of a protruding ridge is formed as a line of defence on the inside; but, before all, to repeat the main point, a strong, resistant internal ring will be obtained which will prevent the formation of a new hernia at the starting-point. Also, the after-treatment is greatly simplified. The muscular parts can be expected to make a firm union in about three weeks.

All I have said pertains to oblique inguinal hernia. Yet there is no reason why direct hernia should not be operated on and be cured in the same manner. Here as well, a pre existing fossa becomes attenuated and finally perforated. The difference, of course, is that another point of the abdominal wall will have to be split. In neither instance is hemorrhage of any severity to be feared. The epigastric artery remains untouched on the inner surface of the flap. But even if it, or any other large artery, should be cut, its ligation is a matter of no difficulty.

The following case was operated on after the principles laid down in this paper, though, to be honest, all my cases operated on after McBurney's method, have proved, up to date, to be perfectly satisfactory.

H——, a German gardener, forty-nine years of age, ruptured by traumatism thirteen years ago, was operated on in the John Sealy Hospital, with the kind assistance of Drs. Cooke, Sykes, and Wysong, on the 6th of May, the operation lasting about half an hour. The oblique inguinal hernia was scrotal, but easily returned. The canal was represented by a hole admitting three fingers, and, as one of the examining gentlemen remarked, a perfect intra-abdominal exploration in addition. I opened the sac more from usage than from necessity. It was then tied *in situ*. The further steps were exactly as described above, including the pillars in the splitting and suturing. No drainage. Patient could not be prevailed upon to keep in bed, but got up whenever he wished to attend to the evacuation of bladder and rectum. A subcutaneous abscess, no doubt due to some skin excoriations from the truss, demanded some attention. Otherwise there was not the least trouble experienced. The sac, being left undisturbed, was quite swollen in the beginning but grew smaller by and by, and shrunk sufficiently to cause no discomfort. The patient was up and about in two weeks without a truss. He underwent an operation for fistula in ano, by Dr. Cook, before he left the hospital, where he had been about three weeks.

The canal is at present so narrow as not to admit a pencil, and judging from external examination, it is well filled through its whole length, and is of normal obliquity. The man has worked steadily since leaving the hospital.

Eighteen Hundred Pounds of Gold is the amount consumed annually for teeth fillings in this country, according to the estimate of a French statistician. This is worth about half a million dollars, and is lost as effectually as if it were dropped into the ocean. The question occurs, how long a time it will be before the cemeteries will contain more gold than the mines.

Rupture of the Linea Alba.—Dr. Monsell has reported, in the *Australasian Medical Gazette*, the case of a woman in whom there occurred a separation of the two halves of the rectus abdominis muscle during labor. On palpation of the abdomen the coils of the small intestine could be felt directly under the fingers, separated from them only by the skin and peritoneum.

INTERCHANGEABILITY OF HEREDITARY TRANSMISSIONS.[1]

By JOHN FRANCIS BURNS, M.D.,

LATE INTERNE AT CHARITY HOSPITAL; PHYSICIAN TO THE INEBRIATES' HOME, FORT HAMILTON, N.Y.

A DEMAND for stimulation by alcohol in the human body is expressed as a morbid craving of the mind. This craving is not in itself an evidence of a diseased brain, but simply an indication of the desire for stimulation by the general nervous organization, which finds its expression in the controlling centre of that system. A craving for food in the human body is expressed by a sensation which we attribute to the stomach, but the actual demand arises from every individual cell throughout the economy. The same holds true in those having an alcoholic craving: the actual need is to be found in peripheral nerve-cells in every part of the body, and similarly with food, the sense of need in the central organ is blunted upon the introduction of alcohol into the system. The difference lies in the fact that the food craving is a normal one, the alcoholic abnormal. The final distribution of the alcohol taken into the system is effected through the agency of the circulation, its consumption occurring principally in the peripheral nerve-cells.

Corroborating evidence supporting these statements may be found in the general histories of drinkers, a microscopic examination of their tissues and nerves, and by a careful study of the different phenomena presenting themselves in individuals suffering from affections produced by indulgence in alcoholic drink.

Drinkers, as a rule, begin in moderation, and do not become confirmed until the general nervous system is so involved that the demand is imperative, arising as it does from repeated over-stimulation of originally deficient cells. The increased quantity of alcohol necessary to produce that quietude sought after in excessive drinkings, indicates the waste of nervous structure brought about by repeated indulgences. The stimulant accomplishes the desired object, but at an additional loss of nervous function proportionate to the amount of indulgence. A man with the tremor produced by alcohol (which tremor it is capable of producing in common with many other poisons) is relieved of his tremor upon the introduction of a fresh supply of alcohol into his stomach. The cry from the nerve-cells has been heard, and the condition relieved, but the relief will last only until the alcohol is consumed in the ultimate cells; and as degeneration instead of regeneration occurs in the cells by the use of alcohol, the demand will increase proportionately with the consumption. A microscopic examination of the terminal nerves of a drinker will reveal destructive changes in cell-structure, consisting principally in degeneration of protoplasm with substitution of a granular fatty material of a low order of vitality; or the nerves are found shrunken and hardened, owing to an abnormal increase in the cell-elements, with subsequent contraction.

Diseases of the nervous system which can be definitely traced to indulgence in alcohol involve the terminal nerves more particularly. Paralysis of the extremities is common, and sight and hearing either temporarily or permanently interfered with, through implication of the optic or aural nerves. Cutaneous anæsthesia and hyperæsthesia are the most common and constant manifestation of alcoholic abuse. The symptoms of cerebral origin are not so marked, and consist mainly in loss of memory for recent events, with delusions concerning immediate surroundings. Events remote are quite readily recalled and dwelt upon rationally.

The condition seems to be one in which the power of receiving impressions and transmitting ideas is lost, rather than an inability to conceive them. The brain first regains its normal balance when alcohol is withdrawn and appropriate treatment instituted, while the more remote portions of the nervous system are the last to regain their normal tone, the cutaneous symptoms often persisting for months and even years.

That the brain of the drinker suffers proportionately with the rest of his nervous system is to be expected, but that the brunt of the attack should be borne by this organ (as is so often taught) is not so evident. It is protected in part by that compensating law of nature which provides for the support and continuance of the higher developed forms of structure at the expense of the lower, and in part from the fact that the ill results attaching to the use of liquor are expended on the general nervous system, and not locally.

If the alcohol drinker's brain were the constant and most vulnerable site of attack, it would require a doubling and a trebling of the lunatic and imbecile asylums of our land for the accommodation of thousands who are now considered eminently successful in business and social circles. The hardest and most constant drinkers are not to be found within the walls of inebriate homes, but are engaged in business, or are men of leisure in society.

All this simply goes to prove that continuous indulgence in alcohol induces alteration in the tissues of the body, which find their expression in a variety of diseased conditions involving the nervous system more especially, and contributing materially to continuance in the indulgence. Now, it is a most curious, yet interesting, fact that diseased conditions of the nervous structures identical with those produced by alcohol, may be induced in the body by substances entirely dissimilar, physically or chemically, from alcohol, and the various conditions so produced cannot be separated in a pathological study. Arsenic introduced into the system in quantity will induce a paralysis and destruction of nervous structure with exactly similar symptoms and appearances. Diphtheria (which is in itself a disease) often leaves a regular condition and symptoms of the nervous system which can in nowise be distinguished from the two previously mentioned. The difference in the name of the disease will be regulated according to our knowledge of the causative agent responsible for the production of the condition; but from a mere study of symptoms, or a microscopic study of the changes wrought in the nerves, we would be unable to state whether the condition was produced by alcohol, arsenic, or diphtheria. A history furnished, or chemical analysis of the stomach contents, might solve the question, but the fact remains that symptomatically and microscopically there exists no essential difference. These conditions, produced by vastly dissimilar substances, are all denominated "diseases" by medical men, under the common title "neuritis," and the neuritis will be alcoholic, arsenical, or diphtheritic, in accordance with our knowledge of the agent responsible for its production. The intimate relationship existing between these and other nervous conditions, both in their visible symptoms and invisible effects, yet produced by so strikingly dissimilar agents, has been demonstrated to the satisfaction of the medical profession, and is well understood and admitted as scientifically accurate. From this we would be led to believe that there are certain fixed laws governing and regulating the destructive changes occurring in our bodies, as there are similar laws governing the reproductive, developmental, and reconstructive processes taking place therein. This is what we would be led to expect from a general study of physical and pathological laws. The human body is not influenced at haphazard by excitants, or irritants from without, any more than it is influenced in a different manner by each individual irritant. If the destructive changes wrought in the tissues of the human body were accomplished differently, varying with each specific cause, we would have such a multiplicity in cell destruction that we should be obliged to give up their study in despair. A certain relationship exists, however, between these destructive pro-

[1] An address delivered at the International Medical Temperance Congress, Staten Island, N. Y., July 15, 1891.

cesses, no matter what the nature of their production, or whether the physical or mental system be involved. Destructive changes assume one of two forms, either there is a multiplication of the cell elements of a part, or there is degeneration in cell-constituents with substitution of effete material. The result is the same in either case, interference with function of the organ or system, and an incapacity to meet the normal demands made upon it without stimulation. We may have this condition produced by causes acting on a previously healthy organization, or the condition occasioning the demand may have been present in the individual from birth, but as a latent, unrecognized defect.

An exact balance of the physical and mental forces in man would not admit of his using alcoholic liquor, for then all his actions would be regulated by his actual physical and mental wants, which would show no departure from the normal. Departure from this normal balance in the physical or mental system is found to produce idiosyncrasy in character or being; when such idiosyncrasies become apparent, and are a source of annoyance to the individual, they assume the importance of a disease. Alcohol drinking is a disease in that it expresses (to a lesser or greater extent) a lack of normality in the nervous structures of the body. The factors responsible for the production of this abnormal condition may be grouped under three divisions—physical, chemical, and social. It has been shown that alterations of nervous structures may be induced in the system by substances other than alcohol, yet without any difference pathologically. This only illustrates a similarity in the method of destruction, but there must of necessity exist primary underlying factors which can be held accountable for the initial condition which demands stimulation. These primary factors are to be found in our physical organization; the secondary and contributory, in chemical irritants and social conditions. They are equally dependent one upon the other, and contribute, though unequally, in the production and continuance of intemperance in the race. Foremost among the physical factors is to be placed that vice of constitution, heredity. The general impression conveyed by this term is that of "direct transmission," that is, that children of drinking parents inherit a predisposition (diathesis) which renders them liable in turn to drink to excess. This view is correct in part, but does not entirely cover the ground, and is confusing. That organizations deficient in vitality, and enervated by excess or disease, will produce successors deficient in vitality, with abnormalities in structure, is a well-certified and demonstrable scientific fact. This holds equally true in vegetable as well as in animal life. Certain precautions taken, or favorable conditions existing, in the life of the successors, may prevent the actual recognition of the deficiency, but it is present nevertheless. The primary protoplasmic cell from which we all spring, as the first recognizable unit of human existence, is dependent for its normality upon the stability of the aggregation of cells in its parents, the union of which is responsible for its existence. The subsequent life of this cell and its products depends in part on the nearness to perfection to which the primary cell approximates, and in part on extrinsic circumstances. While transmission of cell imperfection from parent to progeny so definitely follows, it does not of necessity follow that the imperfection will be transmitted in definite order, or that the manifestation produced as a result of this imperfection will assume a similar form—that is, it does not follow if the parents' nerve-cells be degenerated by alcoholic excesses, that the children of such a parent or parents will evidence this transmitted imperfection in similar manner, in similar alcoholic excesses. The impression is transmitted, but the manner of its distribution will determine where and how the deficiency in the child will manifest itself. The departures and exceptions in transmission of hereditary impressions can only be explained by a recognition of the possibility of an interchangeability in the manner of hereditary transmission. Admit that imperfections in cell-structure may be transmitted from parent-cells to their successors (and this is a fundamental principle in the cell-theory), it must of necessity follow that the original cell from which we base our existence must contain that element in its protoplasm. How, then, can we account for the different manifestations produced by primary imperfection in different offspring from the same parents?

A study of the development of the embryonic cell from its inception will afford us a possible solution. This primary cell increases by the production of cells similar in all appearances with itself, and originating within itself. This multiplication continues until an aggregation of cells exist similar in all recognizable respects to itself. After, however, this self multiplication of the cell has continued for some little time, we notice a process of differentiation to occur—that is, these cells, similar in all particulars, are known to divide into three parts, which begin to assume specific characteristics and functions, being variously modified to meet the requirements of the system they are designed to serve. The three divisions that result represent the three grand systems of the human body, namely, the locomotor, the nervous, and the glandular. Imperfections in the parents' cell-structure may be transmitted to each of the three systems in the differentiation, according to the distribution of the imperfect protoplasm, or they may manifest themselves in two, or altogether, as frequently happens. While we can understand and explain the actual physical changes taking place in the embryo, it is impossible to understand or explain the manner of production of its functional attribute or the manner of the distribution of its primary protoplasm. That function is developed, and distribution of the protoplasm is known to occur, are admitted physiological facts; but the explanation for these phenomena can only be given by our Creator, and are seemingly beyond the reach of science. Alcoholic parents, or parents the victims of other so called vices or crimes, may transmit their peculiar nervous manifestations direct, or they may evidence themselves in one of the other systems, as various physical disorders. Conversely, parents who have never indulged in alcohol, but in whom structural changes have been wrought in the liver, kidney, heart, circulating system, etc., remote from the nervous system, may have the degeneration transmitted and manifested in the nervous system of their children as a condition seeking gratification in morbid excesses or criminal acts. The connection between mental and physical diseases, and their mental interchangeability by hereditary transmission, may be more fully appreciated by keeping in mind the diseased conditions produced in the system by alcohol and various other substances, as cited. All the conditions mentioned, pathologically considered, depend either on a multiplication of cells or their degeneration. Alcohol may produce so-called "Bright's" disease in an individual, or "Bright's" disease may result from causes remote from alcohol. The actual changes occurring in the organization, however, are the same, resulting in destruction of tissue in one of two forms, with impairment of function.

The man having "Bright's" disease as a result of indulgence in alcohol, may beget children who will not have any craving or desire for alcoholic stimulants, but will be deficient physically. The children of the man acquiring "Bright's" disease in cause remote from alcohol may, on the other hand, beget children in whom there will be no noticeable physical defect, but who will have developed to a marked degree the nervous diathesis which predisposes them to excesses in nervous energy. On the other hand, the imperfections transmitted may be evidenced in a variety of ways in the same family. A perfect balance and stability of the cells of the body would preclude disease or excesses of any kind, but the preponderance of elements, or transmitted peculiarities in structure in one system, does not of necessity indicate disease, although it favors it. We have many instances where children of

drinking parents have developed traits of character and habits of application which have carried them far ahead of all competitors in their respective walks in life, while brothers or sisters indulged in excesses which carried with them the physical or mental ruin of the individual. It is possible and probable that these transmissions of imperfections, manifesting themselves in another generation as one sidedness in physical or mental development, are responsible for the production of the brightest intellects. This one-sidedness of character is very aptly illustrated in the so called "genius," who is notably erratic, approximating only in a useful direction to the monomaniac. Peculiar development of mental characteristics depends on something more than mere intellectual cultivation, there is an inherent something in the organization which directs and forces recognition. Environment and circumstance, however, may change a prospective "genius" into a drunkard, or *vice versa*. Excessive development in one direction will bring increase of perfection in that direction, but that this perfection will be transmitted as such cannot surely be expected any more than that an acquired imperfection will be transmitted as a similar imperfection. There seems to exist a conservation of the forces in this interchangeability which, according to circumstance and environment, may develop by transmission good from evil, or evil from good. This mutual interchangeability and dependence of the physical and mental force has an analogous illustration in other natural fields, as in that mutual dependence which is found to exist between the animal, vegetable, and mineral kingdoms, as well as in the intimate relationship and dependence which exist between the various organs and systems in the human body. The acceptance of a law permitting of interchangeability in transmitted tendencies does not invalidate that generally accepted law admitting the transmission of imperfection in cell structure; it only serves to emphasize it by pointing out the variety of results originating from a common source. This conservation of the physical and mental forces, and the methods of interchangeability and compensation, is only another evidence of the merciful kindness of our Creator, evidently designed as an offset to the evil propensities and general neglect of natural laws by mankind in general. If some such law did not exist in nature, man would fast degenerate in a direction in keeping with the circumstances under which we are placed, and which certainly cannot be said to be good.

MEMOIR OF FORDYCE BARKER, M.D., LL.D.[1]

By WILLIAM T. LUSK, M.D.,

NEW YORK.

Dr. Fordyce Barker was born in Wilton, Me., on May 2, 1818. His father, Dr. John Barker, was a busy country physician. He had been for two years an army surgeon, in the war of 1812. As I remember him, he was a man of distinguished presence and of courtly manners. The relations of father and son to each other were in those days ideal. The elder seemed to delight in the exuberant spirits of the younger, while the latter, in spite of his natural gayety, never forgot the reverence of deep filial respect. The motto on the family crest, *Semper constans et fidelis*, seems to indicate that the Barkers were regarded by their neighbors as true and loyal friends.

Dr. Barker's mother, Phœbe Abbott, was an engaging, refined, and intellectual woman. The Abbotts recall the words of Dr. Holmes: "We have in New England a certain number of families who constitute what may be called the Academic Races. Their names have been on college catalogues for generations. They have filled the learned professions, more especially the ministry, from the old colonial days to our own times."

Wilton is situated in a picturesque country not far from the Rangeley Lakes. It is an agricultural community with about twenty-five hundred inhabitants. In recalling the surroundings of Dr. Barker's childhood, it is necessary to bear in mind that in the early part of the century agriculture was still the leading industry of New England. Theological speculations, the Sunday sermons, the town meetings, and divisions of opinion concerning the political theories of Hamilton and Jefferson, kept the faculties awake, and offset the stagnation of rural life. Farmers then read books, and on grand occasions some of them wore ruffled shirts, and did not despise the amenities of social life. Their political ideal was George Washington, and not sockless Simpson.

The Barker homestead was a one and a half story house. It stood on a hill top and commanded an extensive view. In the rural scenery surrounding that isolated domicile there must have been much to feed the imagination of the young boy.

There were no regular schools in Wilton, so Fordyce's early training was conducted by his parents, and no boy ever had better teachers. He had read the New Testament aloud to his mother by the time he was six years of age. His father was a great lover of books, and knew how to impart to the son his own fondness for reading. The rule of the house was stern, but tempered by affection. The beautiful mother writes in her diary, May 2, 1819: "My little Fordyce is one year old this day. O Lord, I do not ask length of days, riches, nor honor for him, but be pleased to grant me this petition. . . . If his life shall be spared, may he seek the Lord, in his youth, and flee from the vanities of this deceitful world. Bestow upon him, O Lord, a meek and docile disposition, one that delighteth in the ways of godliness."

At eleven years of age he was sent to China, Me., where he began his classical training under the tuition of his uncle, John S. Abbott, afterward a prominent lawyer at Norridgewock and Boston. At the end of a few months he was, however, withdrawn and placed at a school which had been opened by Professor Green at Farmington, seven miles from Wilton. While there he was an inmate of the family of an aunt (his mother's eldest sister), for whom he ever retained a warm affection. In September, 1832, he was sent to Limerick, Me., sixty to seventy miles from his home. It was thought at the time that he would still need two years to complete his preparation for college, but thanks to his diligence and aptitude, he was able to enter Bowdoin the following year. In Limerick he made his home with the Rev. Charles Freeman, the pastor of the Congregational Church, who had married another of his mother's sisters. Mr. Freeman was a rare scholar, and his wife was a highly educated and accomplished woman. It is interesting to note that in early life the boy's natural gifts received their full development by wholesome training, and by intercourse with cultivated, scholarly people.

In 1833, at the age of fifteen, young Barker began his college career. Bowdoin, his Alma Mater, was a small college, but as Daniel Webster said of Dartmouth, "there are those who love it," and the faculty of Bowdoin College in those days was one in which a man might in after life take a just pride. The President, William Henry Allen, was a typical scholar, and was possessed of enormous industry. He collected 10,000 words not contained in standard dictionaries; his "American Biographical and Historical Dictionary" contained 7,000 names; in "Junius Unmasked" he sought to prove that Lord Sackville was the author of the famous letters; and besides these better-known of his works, he wrote sacred songs, biographies, poems, and memorial addresses without number. Longfellow and Daniel R. Goodwin held in succession the chair of Modern Languages; Alpheus S. Packard was Professor of the Ancient Languages; Thomas C. Upham taught metaphysics; and Parker Cleaveland—of whom Longfellow wrote the well-known lines, "For him the teacher's chair became a throne"—was the Professor of Chemistry.

[1] Read at a meeting of the New York Academy of Medicine, held November, 1891.

The class of 1837 numbered forty-four, among whom were Governor Gardiner and John A. Andrews, afterward Governor of Massachusetts. All contemporary evidence goes to show that Barker, when a student was a handsome, jovial, winning young fellow, with a beautiful tenor voice. "Sing on, old friend, and enjoy life," one of his fellow-students writes in his class album. Another speaks of his "smiling face," "his hopeful character." And still another wishes that he "may conciliate as many friends in the world as he has in college."

I have heard Dr. Barker disclaim any pretence to scholarship while at Bowdoin. Nevertheless we know that he was at college, as in after-life, a great reader, with a wonderfully retentive memory, and with a natural gift of eloquence. He was only fifteen years of age when he, in response to their invitation, delivered the Fourth of July oration before the townspeople of Wilton. When twenty-one he was a popular speaker in the Harrison campaign.

After graduation young Barker began the study of medicine. His father had indeed urged him to select another profession, but the scientific bent of the boy's mind was decided. He had shown in college more taste for collecting shells than for Greek construction, and the desire to follow in his father's footsteps came to him as a matter of course.

The Faculty of the Bowdoin Medical School, from which, four years later, Barker received his degree, was made up of Henry H. Childs, James McKeen, Jedediah Cobb, Joseph Roby, John Delamater, and Ebenezer Wells. Of these Delamater was one of the most successful medical lecturers this country has ever produced.

There were in those days no clinical advantages connected with the country schools, but then the preceptorship system was a reality, and a large, varied country practice, such as the elder Barker possessed, afforded abundant material for instruction to an eager, inquiring lad; and in this instance the preceptor was a man exceptionally gifted and wise.

In the youth's professional training, provincial narrowness was avoided by a year spent in Boston, where he busied himself with hospital work, and where, as the private pupil of Professor Bowditch, he gained access to the higher professional circles, which were to him an additional inspiration.

In 1841, at the age of twenty-three, Fordyce Barker received the degree of Doctor in Medicine. Owing to signs of incipient phthisis, he was advised by Dr. Bowditch to establish himself in practice in a locality where the climate was more genial than that of his native State. He accordingly started in the summer-time, on horseback, and rode in a southerly direction. Travel in New England was then still to a great extent by stage, or by personal conveyance. The post tavern was comfortable, and the main roads were fairly good. To a young fellow with a sweet voice, a handsome face, and plenty of letters of introduction to families living *en route*, the journey must have been a pleasant one.

With his arrival in Norwich, Conn., his journey ended. As he rode through Washington Street in the bright morning light, the picturesque Cove, the beautiful old elms, and the fine colonial houses with their extensive lawns, impressed his imagination like a fairy dream. The old town was reported to be singularly free from the scourge of New England, *i.e.*, consumption, and so here our young physician decided to establish his home. No new comer was ever more welcome. The social stiffness of the gentry softened at his good humor and kindly laugh, and the young men of talent quickly became his devoted adherents and his life long friends.

In those days society in Norwich presented many features of interest. There were plenty of Huntingtons, and Trumbulls, and Williamses, and Tracys of the first generation from the big wigs of the Revolution. The Fourth-of-July platform still furnished one or two surviving soldiers of the war for independence. Poor Hannah Arnold was ninety years old and looked like a witch. She lived in a small, mean, red house, and was shunned by everyone—the vicarious victim of the popular hatred for her cousin Benedict. There were one or two relicts who on grand occasions wore gowns with short waists and long trains, that had been carefully preserved for half a century. Asa Fitch had lived many years in France. On his return he reproduced at Fitchville a Yankee version of Versailles, and delighted us boys with a display of the fine manners of the old *régime*. Richard Adams, a West Indian, who read the *Albion* to his dying day, and never surrendered his allegiance to King George, upheld the standard of British politeness. At the head of the bar were Henry Strong and Lafayette S. Foster, both of whom became, later, senators of the United States. The leading clergymen were William F. Morgan, afterward the well known rector of our St. Thomas's, and Parson Gulliver, irreverently termed by the Irish "the red-headed priest," to whose battle against the supineness and indifference of its citizens Norwich now owes what is perhaps the finest free-school system in New England. Dr. Farnsworth was the leading physician—a big-headed, big-hearted, quarrelsome man, intense in his hatred, but with a woman's tenderness of heart. He loved Barker. At the time we are commemorating, William A. Buckingham, afterward Connecticut's great war governor, was training for his future solemn responsibilities by leading in prayer-meetings.

More immediately in Dr. Barker's own set were William and Frank Bond; Edmund Perkins, whose fiery eloquence used to make our pulses throb; Henry Huntington, for many years the Paris correspondent of the *Tribune*, and Louis and Donald Mitchell. The latter was wont to declare that the "dear Fritz" of the Lorgnette's letters was his friend Dr. Barker. My list would not be complete without the name of Captain, afterward General, Daniel Tyler. Tyler was of great service to Barker. He had the buoyant spirit which lifted up the hearts of his friends in adversity; which never doubted their success, and which indignantly stamped under foot the work of cowards and sneaks who seek to effect the ruin of others by insinuation and subterfuge.

I speak of these friends of Barker's youth because they were loyal to him through life, they rejoiced in his prosperity, and were proud of the honors that were showered upon him. And who can say how far a man's success in life is due to his ability to command the fidelity of his friends?

For those who remember Dr. Barker's singular timidity in latter years, as regards the use of the knife, it may seem strange to learn that his early aspirations were to become a surgeon.

On September 14, 1843, he married at Harrisburg, Pa., Miss Elizabeth Lee Dwight, whom he had previously met in Norwich. Her grandfather, Captain Benjamin Lee, was related to the two Pitts, and had been a fellow-midshipman in the British Navy with Lord Nelson and Prince William, afterward the sailor king of Great Britain.

On October 1, 1844, Dr. Barker set sail with his young wife from New York for Havre, in the ship St. Nicholas, of 900 tons burden. Foreign travel was confined then to a comparatively select class, and the long voyages were prolific in lasting friendships. On this occasion our Fortunatus met for the first time Mr. John Astor, Mr. Newbold, the Messrs. Edgar, the Henry Masons, and Mr. Ogden Hoffmann, Jr. In after-life the friendship of youth with these men ripened into a tie of brotherhood.

In Paris, during the winter of 1844–45, he was indefatigable in his attendance upon lectures and clinics. Paris then stood at the head of the medical world. Among the names that lent lustre to its famous school were those of Cruveilhier, Nélaton, Velpeau, Dupuytren, Laënnec, Louis, Trousseau, Dubois, Huguier, Lisfranc, Chomel, and Jobert de Lamballe. Imagine the trans-

ports of an ambitious young man when admitted into such a fellowship!

Dr. and Mrs. Barker made for themselves a pleasant home in the Hôtel de Hollande. In both the social instinct was strong, and the American circle in Paris was most agreeable, so the winter passed rapidly. June and July were spent in travel, and in August they set sail for New York by the Cunard steamship Caledonia. Among the fellow-passengers was Sir Henry Holland.

On their return home a way to the leading practice was opened to the young physician, by the temporary retirement of Dr. Farnsworth, who had previously, as indeed he did afterward, exercised supreme authority in medical matters in Norwich and its vicinity. The next few years were pleasant ones. In Norwich his only son was born; he was trusted by all in his professional capacity; he brought happiness into the sick-room by his gentleness and cheerful spirits; he could tell a good story; he could sing beautifully; he could play the organ, the piano, and the trombone; he had composed music to songs; and it is needless to say he was welcome everywhere.

In Paris he had taken an eager interest in obstetrics and the new department of gynecology. In 1846 he was appointed Professor of Obstetrics at Bowdoin, but filled that office for only one year. He was too busy to spare the time.

In May, 1848, he delivered the annual address before the Connecticut Medical Society. It bore the title: "On Some Forms of Disease of the Cervix Uteri." It possessed the qualities of his later writings. The arrangement was clear, the style was elegant, and the writer had something new to tell. Before the reading of the address the writer had local fame; afterward, he had won distinction.

When, two years later, the organization of the New York Medical College was being effected, the Chair of Obstetrics was offered to Dr. Barker. Its acceptance involved his removal from Norwich, and was strongly opposed by many of his warmest friends. He had already, they argued, a comfortable income, and an ensured future, advantages which it would be foolish to put aside for the hazards of a new fortune. But Dr. Barker was thirty-one, and of a sanguine temperament.

In March, 1850, he moved to New York. His first home was at No. 16 East Eleventh Street, near Grace Church. The New York Medical College was not a success. It had in it, indeed, elements of promise. For instance, the faculty was on the whole a strong one: Carnochan, Peaslee, Childs, Barker, and Doremus were able lecturers, Davis brought with him a fine reputation from the West, and Green had his votaries. But the school did not fill a want, and it received from the profession of the city a step-child's welcome. Aside from the incidental disciplinary advantages, it did very little to further the interests of its promoters. Dr. Barker's own connection with it ended in 1857.

In recalling the medical instruction of those days, it must be remembered that the clinic, in a proper sense of the term, did not exist. The popular teacher endeavored to make good the defect by the recital of illustrative cases from his own practice. These were sometimes thrilling, sometimes pathetic, sometimes humorous. They afforded fine scope to persons of natural oratorical gifts, and it is needless to say that among the old college favorites Dr. Barker was *facile princeps*. As a medical correspondent once stated it, when he came to New York, in the early sixties, it was all Dr. Barker and obstetrics, whereas a dozen years later it was gynecology and Dr. Thomas. But those halcyon days have now departed. At present, with object teaching at the bedside and in the laboratory, the didactic lecturer is rapidly being relegated to the rank of a privileged bore.

From the time of Dr. Barker's first entrance upon life in New York, he often responded to calls made upon him to participate in discussions upon current questions. Thus we find among his early papers a pamphlet termed, "A Plea for Hospitals." It is full of interesting information and of old-time eloquence. I will not quote from it here. Fashions change, and eloquence is ephemeral.

It was my privilege in 1853, while in attendance upon the old Anthon Grammar School in Murray Street, to spend a few months in Dr. Barker's family. His practice was at that time small. It is needless to state to a body of physicians that neither popularity as a teacher nor distinction as an essayist influence the number of visitants in a practitioner's ante-room. Yet no one who knew Dr. Barker then doubted for a moment his ultimate success. He was handsome, ambitious, and hard working. Though he could not be extravagant, there was always a seat at his table for a friend. His loyal wife made everyone welcome. The dinners were unostentatious, but the talk was always good, and to a young lad an education. From the outset he gained admittance to the literary circles of the city. Within a year he was made a member of the Century Club. Donald Mitchell was his dearest friend. He became intimate with Washington Irving; Thackeray, who lectured here in 1855, delighted in his companionship. He was the "beloved Æsculapius" of Dr. Hawks. Old Dr. Francis extended to him the right hand of fellowship. The acquaintances he had made in Europe welcomed him to their homes. When his bachelor friends married their wives became his ardent supporters.

In 1857 he removed from a patient, by enucleation, a uterine submucous fibroid. The woman had previously consulted the most eminent surgeons of London and Paris. They had given her no encouragement. She was the member of a large and influential family. When she recovered, Dr. Barker was adopted by the entire clan. To his dying day these early friends sustained his fortunes, fought his battles, and were jealous of his rivals. From this time forth his career was a succession of triumphs. He was an excellent practitioner, kindly and sympathetic. He was an ingenious therapeutist, with more faith in hygiene than in tartar emetic, or in calomel. He loved his profession, and kept abreast with every advance in science. The confidence and affection he inspired in his patients was almost touching. When in 1866 he held out his hand to help me as a young man, his clientèle included nearly every one that was fashionable or famous.

But in the midst of his prosperity his many little deeds of kindness must not be forgotten. To his readiness to help young men in their early struggles many of my hearers doubtless can personally testify. A few days ago I received the following letter:

"Norwich, Conn., October 24, 1891.

"My Dear Mrs. Barker: It is needless to reiterate the profound sympathy which my wife and I feel for you in the loss of your distinguished husband. Gratitude prompts me however to relate an incident, which occurred to me during the late Civil War, which illustrates Dr. Barker's generosity and patriotism

"After the capture of Fort Pulaski, at the mouth of the Savannah River, by our troops, I returned to the North an apparent wreck from the results of typhoid fever. My physicians said that my days of usefulness were numbered, and that I never should be able to rejoin the Army again. My heart was filled with deep chagrin, but resolution succeeded despondency, and with great effort I dragged my emaciated body to New York to consult Dr. Fordyce Barker. He came to see me, at the Fifth Avenue Hotel, with Mr. Wm. Bond. The doctor carefully diagnosed my case, and then said—with a pleasant smile which I cannot forget—'You must have a wonderful constitution to have survived so much quinine and blue mass, as you have taken; the treatment must be changed at once.'

"A few days later the change for the better was marvellous—I was able to call on him. A week later he gave me a lunch at Delmonico's. Three weeks later I

returned to my command at Beaufort, S. C., in perfect health. Imagine, if you can, my pleased and grateful surprise when, on asking Dr. Barker for his bill, he said to me 'I feel well paid in seeing you strong again. I shall take nothing from you, nor will there be any charge from me for treatment of Norwich soldiers who may desire my services during the war.' What could have been more gratifying to a young soldier who had expected to pay several hundred dollars for the restoration of his health and prospects in life?

"I am, with high esteem, yours sincerely,

"Wm. G. Ely (by A.)."

From my intimacy with Dr. Barker I can affirm that in the days of his prosperity, while his time was precious, and every moment was of value, he never showed impatience when called upon to render professional aid to old friends overtaken by adversity.

In 1857 Dr. Barker took part in a discussion on Puerperal Fever before the Academy of Medicine. The subject at the time excited great interest. The contemporary record states that the hall was crowded. Dr. Barker's address possessed the singular clearness that marked all his public efforts. With great dialectic skill he maintained in the face of the prophets the doctrine of the essentiality of the disease. The views he then expressed interest us, as they furnished the basis and incentive in after years for his great work on the Puerperal Diseases. This, the product of his ripened experience, is probably the best piece of medical literary workmanship this country has produced. To be sure, the doctrine inculcated is now dead, killed by the investigations of Koch and Pasteur, but it must be recognized that it did good work in its time by checking the prevailing tendency to exclusivism, which insisted that puerperal fever was a metritis, or a phlebitis, or a lymphangitis, or some other single form of uterine inflammation.

In 1860 Dr. Barker was President of the New York State Medical Society. In 1861 he was one of the organizers of the Bellevue Hospital Medical College, and lectured in that institution until 1867, when, because of his vocal difficulty, he decided that it would be prudent to give up the regular filling of his professional duties. He continued, however, to give clinical lectures at intervals in the Bellevue Hospital.

From 1860 to the end of his professional life Dr. Barker was engaged in reaping the fruits of his high reputation. His general and consulting practice rapidly increased. When it was known that he was to take part in society discussions he was sure to be met by a throng of sympathetic listeners. The laws of legal evidence had for him a peculiar fascination, and his opinion as a medical expert came to be highly valued. His acquaintance included most of the prominent men of the day. Mr. Seward, Mr. Fish, Mr. Blaine, President Grant, President Arthur, Mr. Bancroft, Richard Henry Dana, David Wells, Oliver Wendell Holmes, and Charles Dickens, are only a few of those I now recall from his intimate associates. In 1858 he began the summer trips to Europe which, with the exception of a single year, were repeated to the time of his death. They did much to prolong his useful life, and made him a host of friends in European countries. Personally, I owe many valued acquaintances in foreign lands to letters of introduction which he gave to me. I know therefore from experience of the love and admiration he excited abroad as well as at home.

In 1873, Dr. Barker associated with him Dr. A. A. Smith. The union proved a fortunate one. Through the fidelity and devotion of the younger man, he soon found himself relieved from a large amount of detail work, and whit time to devote to the general service of the profession, and to the boards of many of the great charities of the city.

In 1876–7, he was President of the Gynecological Society. In 1879, he was called to the presidency of this Academy, an office he filled for six years. They were years of unexampled prosperity. Under his benign rule, membership in the Academy came to be regarded as a coveted honor; the meetings were crowded; the papers read were of a high order. He was probably the best presiding officer the medical profession in New York has ever possessed. His kindly disposition calmed troubles in the council chamber, and softened the asperities of debate. In the negotiations for the library of the Medical Journal Association, I again speak from experience when I state that it was his patience and unruffled temper which secured for the Academy that priceless treasure.

He received the degree of LL.D. in 1878 from Columbia College; in 1884 from Edinburgh on its 300th anniversary celebration; in 1887 from Bowdoin on the occasion of the fiftieth anniversary of his class; in 1888 from the University of Glasgow; and a similar compliment was offered him by the University of Bologna on its 750th anniversary, but he was prevented by illness from being present for its reception.

In 1885, I called on Dr. Barker in London. He was living in an apartment in a retired part of the city, 19 Fitzroy Square, as he wished to be out of the way of callers and invitations, that he might have leisure to complete a new work upon which he had been some time engaged. I was much impressed with the unwholesome appearance of the house, and the forlornness of its surroundings. An illness followed a short residence which left him with impaired health. For three or four years he continued in active practice, and his home was the scene of its wonted hospitality. Then came the time when he was obliged to measure his strength. He never, however, abandoned his profession altogether. He still called professionally on his old friends, took part in consultations, and received patients at his office; but it was the work of a brave soul battling with adversity. To the close of his life his intellect remained clear. On Wednesday, May 28th, he dictated a letter to a physician seeking counsel. He died on May 30, 1891, a few minutes before three. He was conscious until nearly noon. Two years previously he had been confirmed by Bishop Potter in the Episcopal Church. All his life through he had studied with the keenest interest the problems of a future state. Bishops Lee, Clark, Bedell, and Brooks, and Doctors Morgan and Hawks had been his devoted friends. There was no sharp break in his life when he took his first communion, but toward the end, when in anguish and pain, his religious faith gave him the fortitude to bear his burden with dignity, without complaint, and with beautiful resignation.

My poor words can add nothing to his fame. They have been written with reverence and tenderest affection.

Some of the Societies and Organizations to which Dr. Fordyce Barker belonged.—The Century Club, one of its oldest members, in 1851; Fellow of the Academy of Design, New York City, 1864; American Geographical and Statistical Society, May 15, 1850; American Bible Society, Life member, June 12, 1867; St. John's Guild, member, June 20, 1871; University Club; Church Temperance Society; Charity Organization Society; Life member Metropolitan Museum of Natural History; Physicians' Mutual Aid Association; Fellow of the London Medical Society, November 4, 1878; Member of London and Edinburgh Obstetrical Societies; Corresponding Member Philadelphia Obstetrical Society, January 5, 1874; also Fellow or Member of the Royal Society of Greece, and elected President of the Anglo-American Society of Paris for the meeting of October 6, 1890, unable to be present.

List of the Published Writings of Dr. Fordyce Barker.

1848. On Some Forms of Disease of the Cervix Uteri. (Address as President of the Connecticut Medical Society, May, 1848, and printed in the Proceedings.) 8vo.

1851. A Plea for Hospitals. (On the necessity for a new hospital in the City of New York.) New York.

1853. Lectures on Uterine Displacements. Reported by B. T. Roath. Lecture First. (Reprinted from New York Medical Gazette.) New York: Baker, Godwin & Co. 23 pp., 8vo.

1854. On the Induction of Premature Labor. (American Medical Monthly, New York, 1854, vol. i., pp. 270-275.)
1857. A Case of Fibrous Tumor of the Uterus, Accompanied with Excessive Hemorrhage, Successfully Treated by Excision. New York. 8 pp., 8vo.
1857. Remarks on Puerperal Fever before the New York Academy of Medicine, October 7, 1857. (Reprinted from American Medical Monthly, New York, November, 1857.) New York: E. P. Allen. 23 pp., 8vo.
1858. On the Comparative Use of Ergot and the Forceps in Labor. Address as the President of the New York State Medical Society, February 12, 1858. (Reprinted from the American Medical Monthly. New York, 1858.) New York: H. B. Price. 16 pp., 8vo.
1858. Remarks on Puerperal Fever before the New York Academy of Medicine, October 6, 1858. By Fordyce Barker and A. K. Gardner. New York. 16 pp., 8vo.
1861. On the Use of Anæsthetics in Midwifery. Read before the New York Academy of Medicine, November 20, 1861. (Transactions of the New York Academy of Medicine, vol. ii., part 8, pp. 251-268.) New York: S. S. & W. Wood. 8vo.
1861. An Effort to Shorten the Duration and Diminish the Pain of the First Stage of Labor; with a Record of One Hundred and Forty-seven Cases. (American Medical Monthly and New York Review, 1861, vol xv., pp. 1-9.)
1864. The Rise in Harlem—a Comedy.
1870. On the Treatment of Croup. A Letter to Professor A. Jacobi. New York: W. A. Townsend & Adams. 16 pp., 8vo.
1870. On Seasickness: A Popular Treatise for Travellers and the General Reader. New York: D. Appleton & Co. 36 pp., 12mo.
1871. Blood-letting as a Therapeutic Resource in Obstetric Medicine. (Reprint from New York Medical Journal, 1871.) New York: D. Appleton & Co. 14 pp., 8vo.
1874. The Puerperal Diseases: Clinical Lectures Delivered at Bellevue Hospital. A Course of Lectures Valuable alike to the Student and the Practitioner. (This work is now in its fourth edition. It was republished in London. A German translation was issued at Leipsic, an Italian at Milan, a French at Paris, a Spanish at Madrid, and a Russian at St. Petserburg.) New York: D. Appleton & Co. xiii., 526 pp., 8vo.
1875. The Relation of Puerperal Fever to the Infective Diseases and Pyæmia. An Address Delivered at the Obstetrical Society of London, July 7, 1875. Louisville. 15 pp., 8vo.
1876. Vaginal Hernia or Vaginal Enterocele. Remarks before the New York Obstetrical Society, on a case communicated by B. A. Clements, M.D., Surgeon U.S.A. June, 1876.
1876. Annual Address before the American Gynecological Society as Its First President.
1877. Relation of the Urinary Organs to Puerperal Diseases. Remarks on Paper of W. M. Chamberlain, A.M., M.D.
1877. Discussion on the Influence of Medicines, Particularly Narcotics, on the Infant, when Administered to the Mother during Pregnancy and Labor. By Drs. Mundé, Barker, Peaslee, Gillette, Thomas, and others. (Reprinted from American Journal of Obstetrics, New York, 1877, vol. x.) New York: W. Wood & Co. 37 pp., 8vo.
1878. Remarks on Obstetric Forceps. Tarnier's new instrument. (American Journal of Obstetrics and Diseases of Women and Children, January, 1878.)
1878. Induction of Premature Labor in the Albuminuria of Pregnancy. (American Journal of Obstetrics and Diseases of Women and Children, July, 1878.)
1879. Inaugural Address Delivered before the New York Academy of Medicine, January 16, 1879. New York: Printed for the Academy. 14 pp., 8vo.
1880. Puerperal Malarial Fever. (American Journal of Obstetrics and Diseases of Women and Children, April, 1880.)
1881. Second Inaugural Address, Delivered before the New York Academy of Medicine, February 3, 1881. New York: Printed for the Academy. 20 pp., 8vo.
1881. Address on Behalf of Street-cleaning, April 13, 1881.
1885. Valedictory Address as President of the New York Academy of Medicine.
1886. Influence of Maternal Impressions on the Fœtus.
1887. Address at the Opening of the New York Cancer Hospital, December 6, 1887.
1890. Address at the Opening of the New York Academy of Medicine, January 17th.

A collection of Dr. Barker's papers were translated into German by P. Sprangenberg, and published in Berlin in 1866. Another collection was translated into Italian by Alesandro Camusso.

A Sad Mistake.—A writer in the *Hospitals Gazette* quotes the following story, said to have been related by Sir Richard Quain, M.D., which perhaps points a moral. He was attending the wife of an old patient, and at one of his visits the husband set him thinking by saying to the doctor, "I greatly appreciate the anxiety you feel for my poor wife, but do not let her see it again, for after you left the room she asked if you were the undertaker." As Dr. Quain rather prided himself on having a good bedside manner, he felt that he was being taken down a peg or two.

Progress of Medical Science.

The Rôle of the Liver in the Production of Urea.—Until the time of Prevost amd Dumas, it was believed that urea was formed in the kidney. These physiologists proved, by their experiment of removing the kidneys in animals, that urea is preformed in the blood or in the tissues, and from that day the kidney has been regarded rather as a filter than as a secreting organ destined to elaborate substances not previously existing in the blood. Subsequently the doctrine was promulgated that urea is formed everywhere in the economy where nitrogenous waste is going on, its sources being metabolism of tissues and of unassimilated food proteids. The muscles were believed to constitute no inconsiderable source; Wurtz's observation that lymph contains more urea than blood is suggestive of a direct relationship between urea and tissue metamorphosis. The facts which have given rise to the belief that the liver is the principal, if not the only, producer of urea, may be briefly stated as follows: It was discovered, as early as 1846, that the urine of persons affected with chronic hepatitis contains little or no urea; twenty years later Meissner, basing himself on accurate analyses of the urine in acute yellow atrophy of the liver, laid down the law that destructive diseases of the liver entail diminution or suppression of urea. Bouchardat, in 1867, proclaimed that certain lesions of the liver are attended with augmentation of urea-production, while others cause diminution. Brouardel and Murchison enriched medical literature by new observations, showing "that the quantity of urea secreted and elimmated in twenty-four hours is dependent on two principal influences: the state of integrity or alteration of the hepatic cells, and the greater or less activity of the hepatic circulation. In those cases which are characterized by augmentation of urea, the liver has not been found to be the seat of grave organic lesions, but only of simple functional disturbances, a hyperæmia, it may be, similar to what is observed in a certain number of cases of diabetes. In one case of spasmodic icterus, Bouchardat noted the enormous quantity of one hundred and thirty three grammes of urea in the twenty four hours, and the excretion continued in this proportion for three or four days. Fourcroy and Vauquelin also announced about the same time (1846) that in icterus the urine may contain a very large proportion of urea. Fouilhoux subsequently reported a case of simple hepatitis in which the figure of urea was double the ordinary. Facts of the second group—where there is diminution of urea—belong to cases of destructive lesions of the liver, where the whole extent of the hepatic parenchyma is affected. Under this head we find acute yellow atrophy of the liver, common cirrhosis, cancer of the liver which has invaded large portions of that gland, hydatid cysts, abscesses of considerable dimensions, granulo fatty degenerations of the liver, whether following grave infectious fevers or induced experimentally in animals.

Meissner's treatise contains the principal observations which have been made on animals confirmative of the pathological observations above mentioned. According to this authority, urea is not found in the muscles or in the lungs of mammals, but almost exclusively in the liver. In the liver of a dog which was bled to death, several centigrammes were obtained; the organ was carefully washed, and the vessels flushed out with warm water before being subjected to analysis. The results obtained by Meissner have been confirmed by Cyon, who concludes "that there is a real and rapid production of urea in the passage of the blood through the liver." Cyon appeals to facts similar to those adduced by Claude Bernard, to prove that the liver produces sugar: the blood of the hepatic vein is found to contain more urea than the blood of the vena portæ.

Lecorché and Talamon do not dispute the proposition that the liver produces urea, or that there is more urea

in the hepatic than in the portal vein; they do dispute that the liver is the sole or the principal urea-forming organ. To the statement that in destructive diseases of the liver there is a diminution of urea, they oppose careful observations of their own, where, despite such destroying lesions (diffuse cancer, diffuse venous cirrhosis), the quantity of urea remained normal. This fall in the proportion of urea, of which Murchison and Brouardel make so much in its application to serious hepatic lesions, is equally characteristic of every disease of long duration, of every cachexia, cancerous, tuberculous, or otherwise; it is, however, true, as a general rule, that in affections which alter the structure of the liver, the fall in urea-production is a little greater than in the chronic diseases of other organs. This is easily explained on the ground that the liver is an organ of great magnitude and importance; "it is quite natural that the quantity fabricated should fall considerably when a centre of formation so important is suppressed; but it will not do to push too far the consequences of this fact, and make ureopoiësis, that is, urea making (from the Greek), a special function of the liver." In fine, the diminution of urea, and the appearance of leucine and tyrosine and extractives in the urine are not accidents proper to acute yellow atrophy or other wasting diseases of the liver; "but simply an episode of the general perturbation imposed on the phenomena of disassimilation of the entire organism by the infectious disease."

Lecorché and Talamon next take up the facts adduced by Murchison and others, from which the conclusion is drawn that in states of hyperæmia, or excitation of the liver, the production of urea is exaggerated. This they admit to be true, but "polyuria, with augmentation of urea, is not peculiar to hepatic affections, being only a critical phenomenon, such as may be observed in any other acute disease; lastly, if physiology seems to have demonstrated that urea is formed in the liver, clinical observation does not permit us to believe in a special function of that gland, but only in a phenomenon of disassimilation, such as takes place likewise in the intimate substance of all the tissues of the organism." This, then, which is really the older doctrine, may, we think, be regarded as the latest authoritative teaching of science respecting the puzzling question of the sources of urea in the economy.—*The Boston Medical and Surgical Journal.*

Desquamation en Masse of the Urethral Mucous Membrane.—Dr. Boulland reports a curious instance in which the lining membrane of the urethral canal was shed as a whitish cylinder fourteen centimetres in length and three millimetres in diameter. The patient was a man aged twenty-eight, whose gonorrhœa had been treated for a long time by astringent injections, and who was finally given a bichloride solution, 1 to 3.000. Two days after this was injected there was difficulty in urination, and an obstacle seemed to occupy the canal. This was finally forced out, and was found to be a tube whose walls were formed of epithelial cells which had undergone fatty degeneration, and of a few connective-tissue fibres. Shortly after this occurrence the cure was complete.—*Limousin Médical.*

Nasal Polypus and Hysteria.—Dr. Marcel relates the case of an hysterical girl of twenty-three, who for seven years had suffered from frequent attacks of convulsions with loss of consciousness. The convulsive seizures were preceded by an aura starting like an itching or tickling in one side of the nose, and extending to the eyelids, and thence to the throat, where it caused a sense of suffocation. A polypus was discovered in the corresponding nasal fossa, and upon its removal the attacks ceased.—*Medezina.*

The Squirters of Koch's Lymph is the term applied by an unappreciative Southern contemporary to the gentlemen who are still experimenting with tuberculin.

Clinical Department.

SWEET OIL IN THE TREATMENT OF BILIARY COLIC.

By P. J. McCOURT, M.D.,
NEW YORK.

An editorial article in the MEDICAL RECORD of October 24, 1891, p. 513, under the above heading, referring to the investigations of Drs. Mays and Bloom, induces me to offer my experience with this remedy.

For the past nine years olive oil is the specific remedy I have prescribed in the treatment of biliary colic. A very considerable number of cases, all of women, have been in my care during that time; and in no instance has the pure oil failed me when directions were strictly obeyed.

My uniform mode of administration has been as follows: The patient is prepared for bed, receives a three-ounce dose of the oil, lies down instantly on the right side, with a slight inclination backward, the pillows being removed from the head and placed under the crest of the right ilium, thus elevating the pelvis, favoring the regurgitation of the oil from the duodenum through the common bile-duct, the hepatic, and cystic ducts, and the conveyance of the remedy to the obstructed viscus.

Morphia, hypodermically, is given when necessary to subdue pain; but this is rarely essential, and relief is usually complete in about an hour—often in thirty minutes.

On the morning following, or from five to eight hours after the oil has been taken, a brisk cathartic, or even a Seidlitz powder, will produce evacuation of the gallstones and relieve the case.

If, on the other hand, the patient, after taking the oil, is permitted to walk about, or sit up, or even retire without maintaining the position indicated, the results are often *nil*, and a correct repetition of the remedy is necessary to insure success.

I infer that cotton-seed oil is not "just as good," from the fact that olive oil of inferior grade (usually adulterated with cotton seed oil) has rarely afforded relief, while the pure oil, which has a yellow or greenish-yellow tint, has always done so.

I can also vouch for its efficacy as a prophylactic. To persons subject to the disease I have repeatedly ordered the oil—about every third month—in the absence of all symptoms; and very frequently in such cases have biliary calculi, usually of small size, been expelled.

REPORT ON A CASE OF POISONED WOUND BY THE BITE OF A RATTLESNAKE (CROTALUS).

By CHARLES ALBERT SEWALL, M.D.,
ACTING ASSISTANT SURGEON UNITED STATES ARMY, FORT WINGATE, N. M.

Private Ross, Troop C, Second Cavalry, while lying asleep under a rock on a very hot day, the command having halted at Sheep Springs, about forty miles from Albuquerque, N. M., reported that he had been bitten by a rattlesnake about four feet long, and had secured the rattles after killing the snake. The rattles were eight in number. The patient exhibited considerable anxiety, pulse small and thready. Two wounds of about one-eighth of an inch in length each were found at the base of the index-finger of the left hand, dorsal surface. The wounds were about one-half inch apart, and evidently caused by the fangs of the serpent. The swelling was slight, and the hand was red and slightly ecchymosed. The man stated that as soon as he saw the wound be began to suck it violently and continued to do so up to the time he saw me. A ligature was immediately placed about the wrist. Eight drops of ammonia liquor were given in water by the mouth, and the same applied on lint to the wound. Emesis was produced and the hand began to grow black. Ten

minutes afterward whiskey, one ounce, was given in water. The pulse came up at this time and the patient was placed in the ambulance and proceeded on the march, as the command began to move. Whiskey was given every two hours afterward, and no bad symptoms except sick stomach occurring, the man was left and allowed to go to sleep, as the whiskey began to have an intoxicating effect. I must remark that about two hours after the injury the man complained of a numb feeling all over the body, which was dissipated by repeated doses of whiskey. A partial attack of blindness and difficult locomotion came on the night of the injury about 8 P.M., but was soon recovered from. A feeling of nausea lasted about four days, and at the end of that time the soldier was returned to duty apparently well.

Remarks.—1. The sucking of the wound so vigorously by the patient had certainly a very happy effect in preventing the entrance of but little of the poison into the blood. 2. The ligature contributed in a measure toward the same result. The stimulants acted admirably. It is estimated that the whole amount of whiskey taken was eight ounces.

The amount of the venom taken into the stomach while sucking the wound it is believed produced the nausea and anorexia, which lasted until the fifth day after the injury.

A CASE OF HÆMATOMA AURIS WITHOUT MENTAL DISEASE.

By L. W. SPRATLING, M.D.,

ASSISTANT SURGEON UNITED STATES NAVY, VALPARAISO, CHILI.

THE following case of hæmatoma auris has come under my notice, and I report it for its lack of connection with any mental disease. A. B—— is a seaman in the United States Navy, and was born at Dublin, September 29, 1861. He first came to the sick bay for treatment on the evening of April 27th, saying his right ear was very painful. It had begun to pain him two hours before, but at that time he didn't notice anything unusual.

Examination showed the external ear swollen into a red, hot, fluctuating tumor, about the size of a hen's egg. The canal was entirely closed by the swelling. About 10 c.c. of bright arterial blood was evacuated by a small incision at the concavity of the concha, and a bandage put on with the idea of applying pressure and preventing re-formation of the tumor, which was almost entirely reduced by the evacuation of blood. A dose of sulphate of magnesia was given. Next morning the tumor was as large as ever. It was again punctured, and rapidly refilled, and no further treatment was given. On May 6th, the patient was discharged to duty, without pain, and the tumor, very little reduced in size, was more firm. It has gradually contracted, until now, August 15th, the fluctuation is gone and the ear is very much thickened and puckered out of shape. There seems to be a considerable amount of new connective-tissue formation. The left ear was affected in the same way two years ago, and is now in the same deformed condition. Hearing is not affected in either. The patient is a robust fellow, 5½ feet high and weighs 155 pounds, ruddy complexion, gray eyes, sandy red hair, and an intelligent face, a little plethoric probably. He has been a mariner most of his life, and spent the three years preceding the occurrence of the first tumor off the west coast of Mexico and Central America, on the United States Steamship Ranger. Family history good, mother and father living—the latter aged seventy and in good health. Denies ever having had syphilis or rheumatism. He is not a habitual drinker. Had a mild attack of typhoid fever after returning to California from Mexico and Central America. This was after the appearance of the first tumor. He has never had the scurvy nor anything tending to induce hemorrhagic diathesis, and shows no symptoms whatever of mental trouble of any kind.

PROLAPSE OF THE BLADDER IN AN INFANT.

By B. S. ROSEBERRY, M.D.,

LACON, ILL.

A CASE occurring recently in my practice, by reason of its rarity seems worthy of report. I was called to see a child, a female, at whose birth I had officiated twelve days previously. It was a face presentation, but the labor was not particularly tedious and delivery was accomplished without instruments. Inspection at the time revealed no anatomical defect or deviation from the normal in any particular.

On responding to the summons above referred to, I found the child with a protrusion of the anterior vaginal wall and portion of base of bladder through the vulvar outlet, the prolapsed portion being badly strangulated by the constricting action of the sphincter vagina, which grasped it tightly. The condition had existed five hours when first seen by me. At first glance I thought I had to deal with vaginal hæmatocele, but the introduction of the hypodermic needle and the withdrawal of two syringefuls of urine made the diagnosis of vesical prolapse certain. The fluctuating tumor was about the size of a hickory-nut, somewhat flattened laterally, and firmly pressed up in front of and against the pubic arch. The perineum was unusually broad in its antero-posterior measurement for a child of that age, and extremely resistant. By administering chloroform and forcibly pushing the perineum back with the little finger of my right hand insinuated between its edge and the posterior aspect of the prolapsed organ, and by gentle, though firm taxis with the thumb and two fingers of the left hand, I succeeded, without very much difficulty, in restoring the misplaced parts to their normal position, after which an antiseptic absorbent cotton tampon, anointed with vaseline, was placed in the vagina as a support. This was removed in forty-eight hours, and as considerable sloughing was taking place from that portion of the vagina which had been the seat of constriction, the tampon was not replaced. As long as necessary after this the vagina was daily flushed with antiseptic fluid (weakly carbolized water).

The exciting cause of this accident was found in the existence of a diarrhœa, with considerable tenesmus, which had been present for five days. There was, however, no tendency to rectal prolapse, not the slightest eversion of the mucous membrane, which latter, of course, would not have been a matter of any surprise.

The child had considerable temperature for the first week, ranging usually from 103° to 104½° F., but once reaching 106° F. After this it subsided and became normal, remaining so until the death of the patient, which took place from exhaustion, eighteen days from the occurrence of the trouble. Locally the parts did well; the sloughing had about ceased, the bladder retained its position, and the urine was voided naturally.

The child nursed and digested well, but the original shock seemed too great for its infantile recuperative powers, and so a fatal termination ensued. I have not been able to find any similar case reported, and would be glad to know if any of the many readers of the MEDICAL RECORD have met with such a condition in an infant.

The Sei-I-Kwai Medical School, of Tokio, which formerly belonged to the Society for the Advancement of Medical Science in Japan, has recently been placed under the authority of the Tokio Charity Hospital, at the same time changing its name to the Tokio Charity Hospital Medical School.

And Now It's the Druggists' Turn.—The *British Medical Journal* says that the Municipality of Seville has decided to establish two public pharmacies where poor patients may have prescriptions made up for nothing. The local druggists are up in arms against the proposal.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, November 21, 1891.

THE SPONTANEOUS HEALING OF TUBERCULOSIS.

THE late Dr. Austin Flint used to assert that pulmonary phthisis had in some cases a natural tendency toward recovery. This view he based on clinical evidence mainly. Pathological anatomists have long known that healed tuberculosis of the lung apices was not uncommon. In the *British Medical Journal* for October 31st, is a series of articles which contain a good many new and definite facts regarding this subject. Dr. Joseph Coats, for example, going over his records, finds healed tuberculosis in 24 out of 103 post-mortem records. Of these 24 there were 20 cases of pulmonary, 2 of peritoneal, 1 of mesenteric, and 1 of bronchial gland tuberculosis. None of the patients died of tuberculosis, but it is curious to note that four died of gangrene of the lungs.

Dr. J. K. Fowler gives still more extensive figures, taken from the Middlesex Hospital and the Vienna General Hospital:

Middlesex Hospital, 1879–1886.

Number of necropsies			1,943
Obsolete tubercle in lungs			177 = 9 per cent.
Males	110	Right lung	35
Females	67	Left lung	36
	177	Both lungs	106
			177

Institute of Pathological Anatomy, Vienna, 1869–1879 (*Heitler*).

Number of necropsies			16,562
Obsolete tubercle in lungs			789 = 4 per cent.
Males	509	Right lung	69
Females	280	Left lung	65
	789	Both lungs	655
			789

Dr. Fowler makes an interesting analysis of the clinical histories of the Middlesex Hospital cases. The average age he finds to be fifty years, and males were found largely to exceed the females. As to the lung affected he says:

"One result, perhaps somewhat unexpected, but confirmed by Heitler's table, is that the process appeared to be more often arrested when both lungs have been affected than while it is limited to one. It is contrary to clinical experience to find the disease simultaneously attacking both apices and equally distributed through both upper lobes; it is therefore probable that in such cases one apex is affected after the other, and possibly in some cases after arrest has taken place there. It will be seen that there is practically no difference between the two lungs as regards liability to infiltration.

"It will be noted that in some of the cases the lower lobe was already affected, showing that this often occurs at an early period. The fact that the lower lobe (about its posterior apex) is involved is therefore no bar to arrest of the disease."

As to the stage of the morbid process, the writer expresses some very positive opinions—opinions upon which the enthusiastic clinician may well ponder.

In the majority of cases the lesion was fibrous or caseous, and in only forty-three cases out of one hundred and seventy-seven is it stated that a cavity was present. It does not follow that the cavity found *post mortem* was a clinically recognizable cavity, or indeed that any cavity at all existed during the period of activity of the disease. Dr. Fowler believes that in many cases it is a false appearance of excavation, produced by the growth of a fibrous capsule, which becomes smooth within, around a caseous mass. This is often described as a cavity with caseous (often blackish-gray) contents. Dr. Fowler's pathological experience gives little support to the view which is held by some, that a cavity, recognizable as such by physical signs, may become completely obliterated. If one is to believe the stories of patients (which, by the way, it is generally better not to do), some authorities appear to have arrived at such an "altitude" of diagnosis that they can trace (on paper) the gradual shrinking of a cavity up to its final obliteration. One frequently sees a thick-walled cavity which has both contracted and altered its shape, but a cicatrix which appeared to represent what was at one time a clinically recognizable cavity he had not observed.

It is a striking fact, that from fifteen to sixteen per cent. of cases of healed tuberculosis die of cancer. This is noted in the tables of Dr. Coats, Dr. Fowler, and Heitler. In forty-two cases of Dr. Sydney Martin's cancer was the cause of death in twelve.

THE COLD SITZ-BATH AFTER LABOR.

THERE is nothing so absurd or fantastic that it cannot be taken up and seriously recommended as a therapeutic measure by some "experienced" physician. Thus we find that in the *Blätter f. klin. Hydrotherapie* Dr. G. Pingler puts in a powerful plea for the routine employment of the cold sitz-bath immediately after the expulsion of the fœtus. He first commenced this method of treatment in 1850, and after twenty-seven years' experience of it felt himself justified, in 1877, in strongly recommending it—which he did in a pamphlet then published (*Medical Press*). This pamphlet, rather naturally, did not meet with a warm reception; so now Dr. Pingler resumes his plea, and puts in statistics in its support. Two midwives in Königstein, he says, always used the cold sitz bath in this way. One of them has attended thirteen hundred confinements without a single death. Another has attended seven hundred without a single death, although turning and perforation had been called for.

Dr. Fresenius, of Soden, who has also tried it, speaks in most favorable terms of the sitz-bath. He says: "I have tried it in a practice extending over years, and make

use of it on account of its prompt and permanent action in cases of atony of the uterus. The considerable difference between the temperature of the body and that of the water acting reflexly, immediately sets up powerful uterine contractions that stop the hemorrhage. If the placenta is still in the uterus, a little massage of the fundus, and gentle contraction on the cord, suffice generally for the removal of it. If the contraction is permanent the patient is placed on a linen sheet over woollen blankets, wrapped in them, and rubbed dry, and after removal of the sheet, wrapped up warmly in bed."

Post-partum hemorrhages, or diseases of the genital passages, have never been observed after this procedure. Dr. Pingler requires, before making use of the bath, that the patient shall have a bed capable of insuring the necessary reaction, and that above all she shall not be lying on straw; further, that the midwife or other person shall, without much disturbance, see to the establishment of the reaction. For this purpose the hand is to be introduced carefully beneath the clothes, and the hips and thighs and legs well rubbed. If two persons are present, five to ten minutes are generally sufficient for the establishment of the reaction. If this is well established within from ten to thirty minutes, there need not be the least fear that the patient will suffer from the effects of the bath, especially if care be taken that the surface warmth of the patient is equable.

PSYCHIC AID IN NEURASTHENIA.

To lose the joy of living, from whatever cause, is to be poor indeed. To dread waking in the morning, and long to give the sun a blow that will put out its eye, denotes a state far removed from what may be called radiant vitality. Nights full of shadows and days filled with dull despair are not conducive to great deeds.

While neurasthenics may be, as Clifford Albutt calls them, the salt of the earth, they have periods of losing savor to such an extent as to induce in their own minds a doubt concerning this exalted destiny.

The physical symptoms of neurasthenia all receive attention. An effort is made to new-line the gastro-intestinal tract, to drive away the ache or emptiness of head, to electrify lax muscles, to piece out defective vision, and to lessen hyperæsthetic hearing. Everything under heaven is done for the neurasthenic except comfort his lonely soul, said soul having somehow become as solitary as an empty bark in mid-ocean. The sense of complete isolation due to exhaustion of nerve-centres, only to be understood by personal experience, is a keen, murderous condition that exists in proportion to individual sensitiveness. As the sensitive are never sensible, it is well to bear in mind their need, when overthrown, of help from others; help having for chief ingredients earnestness, sympathy, firmness, and good judgment. Sympathy need not necessarily be expressed in words, earnestness can be gentle, firmness may be cheerful and smiling, and good judgment quiet and unobtrusive. Unless someone places such qualities at the disposal of the neurasthenic and allows him to construct from them a moral support, the value of strychnine, bromides, baths, electricity, and even small doses of opium, is greatly diminished, and medical labor more or less in vain.

The mental attitude in neurasthenia is peculiar. The silent resentment that being misunderstood gives rise to, is long in fading away. And when it is gone, it is found that much affection, perhaps all that was really worth while, has somehow disappeared as well. Nothing remains but a scar that is sure to ache in mental bad weather. While the human comedy lasts, the neurasthenic will need at intervals this happy combination in another, of sympathy, earnestness, good judgment, and firmness.

It is useless to hope for psychic aid from the family, except in rare instances. They are alarmed or irritated, and always unwise. It is the physician alone who can come to the rescue. He is at once the doctor of the body and of the soul, and, convinced that nothing is perfectly sure but change, that everything wears to rags, or will melt, fade, disperse into thin air, he raises his patient's tottering faith and convinces him that all former delight in books, friends, music, events, enterprise, and the simple victories of every day living, will one day return. To remove in part the sense of isolation resulting from lowered vitality is to renew self-respect. And equilibrium that is the outcome of self-respect, of consideration for others, of interest in events, and sympathy with the world's workings, grows into permanent self-reliance that means health.

ARISTOL.

This new iodine preparation has now been pretty well tested clinically, and from the numerous reports published, it appears to possess qualities which make it likely that it will not go the way of most new remedies, or at least not right away. Dermatol and euphoren, are similar and more recent iodine preparations which are claiming the attention of the clinical investigator. Whether aristol will be able to maintain its right to the distinction which its name implies, is a question which will be settled, as between these three preparations, in the near future.

Dr. Nadaud has reported to the French Academy of Medicine that he has employed hypodermic injections of an aristol solution in twenty or more cases of pulmonary tuberculosis. In seven instances the improvement was so great that a complete cure was hoped for; in five, improvement was rapid, but symptoms subsequently returned; three were not improved; two died; and six, still under observation, show decided improvement. There are no poisonous symptoms from the injections, it is claimed, and the beneficial results shown by decrease in the cough, cessation of night-sweats, etc., become apparent after the first week of treatment.

Thus aristol is seen not to differ from other new remedies, most of which, sooner or later, become cures for consumption.

LUPUS ERYTHEMATOSUS.

Some months ago we expressed the hope that tuberculin would prove capable of showing whether or no lupus erythematosus was of tuberculous nature. In this the lymph has failed, as it has in doing much else that was expected of it. In the recent congress for the study of tuberculosis, Hallopeau and Jeanselme reported on a case which tends to throw some light on the question. A man who

from puberty had coincidently a typical erythematous lupus and tuberculous disease of the glands, died from acute miliary tuberculosis.

The results of the bacteriological investigations and inoculations which were carried out were positive, so far as the miliary granulations and the cheesy glands were concerned, and entirely negative in the case of the lupus tissue; three guinea-pigs, inoculated with the latter, being found entirely free from disease one hundred and ninety days after.

This would appear to show with some degree of positiveness that the lupus was in no wise of tuberculous nature; but the observers do not draw this conclusion. They believe that the tuberculous contagium is capable of such modification and evolution in the system that it can take on a form non-transmissible to animals. If this be the case the negative results of inoculation have no weight, and we are forced to rely still upon clinical data for our conclusions. Clinically, the relationship between lupus erythematosus in its various forms and tuberculosis would seem to be pretty well established, and these investigators believe that at least one of its varieties is a product of tuberculous infection, and, if it is not inoculable, it is because the contagion has become much attenuated. This is a very convenient theory for those who believe in the identity of all forms of lupus so far as etiology goes, and it is indeed plausible; but it forces us to give up the idea that all products of tubercle are transmissible by inoculation.

VIVE LA MORT!

They do everything well, and in the most airy and charming manner, in Paris, as witness the death of a certain Dr. Bergeron there lately. He had had all he wanted of this earthly existence, life had become to him "as tedious as a twice-told tale," and, so, naturally, he thought he would throw it off. He might have shot himself, or cut his throat, or jumped off the Eiffel Tower, or shut himself up with a charcoal stove, but he didn't. Anybody with the most ordinary intellect, even a German, could kill himself in that way—it would be too common—the papers would hardly notice his death, and there would be no sensation at all. So he bided his time, serenely confident that the opportunity would come, as it always does to the one who can wait.

It came the other day. He was sitting one evening in a café with his mistress and a male friend, when the latter happened to complain of a sore throat. Here, at last, was the opportunity so patiently waited for, and he embraced it at once in the true Parisian style. "Just let me give you a little aconite, old fellow," said he, "there's nothing like that for knocking spots out of a sore throat." So he wrote a prescription for tincture of aconite and sent to a neighboring drug-store to have it filled. He put a couple of drops in a glass of water, telling his friend to sip it occasionally until he had taken it all, and then poured out about half an ounce in his own glass and drained it off, with an indulgent smile at the fears of his mistress, who seemed to think that it might be a little too much for a man in ordinary health.

He presently died, and the papers devoted several columns to a description of the way he did it.

A MOST REPREHENSIBLE PROCEDURE.

The medical West End of London is nearly petrified with horror and amazement at the audacity of a cheap doctor who has invaded these sacred precincts. It appears that this c. d. has organized himself into the "Medical and Surgical Consulting Rooms Association," and has had the nerve to distribute the cards of the said M. & S. C. R. A. all over the neighborhood, "not excepting," says one shocked journalist, "the houses of the aristocracy." This was really too bad—so bad that it actually angered a gentleman, who is described as a county magistrate and a life governor of one of the large London hospitals, to such a degree that he felt compelled to write to his medical attendant, and enclose one of the objectionable cards. He wrote: "The enclosed card was dropped into my letter-box this evening. I feel indignant at the receipt of such a document, calculated as it is to bring odium on your profession. Who, or what, are 'Medical and Surgical Associations?' Surely the working classes require no such aids? They have hospitals and charitable institutions open to them. Is it not a matter for the heads of your profession? Why should gentry have foisted upon them such 'cheap and nasty' documents?" Why, indeed? It was indeed outrageous that any more dispensaries should be opened, and the "heads of the profession" ought to have united to see that the bread was no longer taken from the mouths of their young and struggling confrères by the establishment of any more institutions for free medical treatment.

In looking at the report again, we find that it was not a free dispensary, but a place where sixpence was to be charged for each visit. We now understand better why so much indignation was aroused.

News of the Week.

The Fourth Italian Congress of Internal Medicine met at Rome, October 19th, under the presidency of Dr. Guido Baccelli. The correspondent of *The Lancet* says: "After the usual formalities in constituting the various secretaryships of the sections, Professor Rossoni, of Rome, in conjunction with Professor Forlanini, of Turin, presented their report on 'The Pathology and Cure of the Diseases of the Stomach.' This paper, which forms the chief attraction of the officially published 'Atti' of the Congress, would take too long to summarize here. Suffice it to say that after a review of previous workers in the same field, supplemented by observations of his own made in seventeen years of practice, Professor Rossoni proceeded to show how surgery could be of yet further use than she had hitherto been in the diagnosis of stomachic disease; and, basing his argument on the memorable results obtained by Count Loreta, of Bologna (the initiator of the 'Digital Divulsion of the Pyloric and Œsophageal Orifices'), he insisted on the necessity of the physician being able, when required, to operate in all such cases for himself. Professor Forlanini considered the pathology of the stomach from the chemical side, dwelling lucidly and at length on the determinate forms of gastropathy, due on the one hand to excess, on the other hand to deficiency, of hydrochloric acid. The discussion which followed elicited illustrations, chiefly confirmatory as regards

Professor Rossoni's paper, and controversial as regards Dr. Forlanini's, from Professors Maragliano (Genoa) and Bazzolo (Naples), as well as from Drs. Reale and Ferranini, of the Neapolitan school. The President summarized the whole in an effective review, adding considerations from his own experience in clinical and consulting practice.

"The next day's (20th) proceedings embraced a thesis by Professor Albertoni on the so-called 'Auto-intoxicants,' as seen in the coma of diabetes and in the effects of fatigue. His views were supported and extended by Professor Silva, who cited Professor Mosso's well-known doctrine as to the poisonous nature of the products of metabolism from prolonged muscular exertion; and the subject received further elucidation from Drs Rovighi and Masini, the latter of whom related his experiments by partial and complete suppression of the function of the liver to illustrate the action of 'auto-intoxicants. The discussion, however, became chiefly memorable from Professor Maragliano's contribution to it. He referred to Querolo's studies on the toxicity of the sweat, and on the destruction of what he called the 'hæmatiæ' in the serum of the blood in various maladies; and, *apropos* of diabetic coma, he cited the experiments made by himself with intravenous alkaline injections. Finally he reverted to his favorite suggestion of opportune and graduated venesection, in such cases, as a means of diminishing in the circulation the auto intoxicant elements. The debate was prolonged into the afternoon, Professor Albertoni replying to his critics, and Professor Baccelli, as President, summing up its net outcome, and agreeing with Professor Maragliano, especially on the therapeutic side. The return of judicious venesection to the recognition too long withheld from it is, he thought, a hopeful sign in modern practice.

"The sittings of the 21st and 22d were less interesting in their tenor. At the former the most animated discussions were those occasioned by the report on icteritia (jaundice) by Professors Mya and Patella, and by Professor Maragliano's paper on 'Tuberculosis and the Lymph of Koch,' though this had to be curtailed for want of time. The proceedings of the 22d (the last day) were mainly of a business character. One of its details was the decision as to the subjects to be prescribed for discussion next year. They were three in number: 1, Rheumatism; 2, Cerebral Localizations; 3, Aero therapeutics. After his closing address Dr. Baccelli intimated that the next year's Congress will be a preparation for the great International Congress of 1893, in which the Italian school will be expected to give some account of its contributions to the theory and practice of the healing art."

The Cuban Medical Congress, which was to have been held in Havana in January, 1892, has been postponed to the following autumn. It is proposed to hold it in October, 1892, coincidently with the quadricentennial celebration of the discovery of America.

Instituto Italiano.—The Italian Home at 179 Second Avenue, which was opened by the Italian residents of New York on May 1, 1890, as a hospital and dispensary for the care of their destitute countrymen, has become a very flourishing institution. During the first year 4,053 persons were assisted, 1,619 at the hospital, 899 at their homes, and 1,535 by their special agency at the Barge Office. With the Italian population in this city reaching a figure not far short of 80,000, and with the constantly increasing flow of immigrants through the city bound for points in the interior, such a hospital has been established none too soon, and its well filled wards testify to its being appreciated. On the evening of November 10th the consulting physicians of the hospital were handsomely entertained at a banquet tendered by the officers, council, and medical staff, and presided over by the president, Mr. G. Starace. Speeches were made by Count Naselli, the Italian Vice-Consul, Signor Giacosa, the poet, and Dr. Attinelli, Physician-in Chief, and a number of others. The consulting staff consists of the following gentlemen: Charles W. Allen, Hermann M. Briggs, William T. Bull, A. G. Gerster, Virgil P. Gibney, John W. S. Gouley, Edward L. Keyes, Hermann Knapp, Alfred L. Loomis, Prince A. Morrow, Paul F. Mundé, Newton M. Shaffer, Lewis A. Stimson, Bernard Sachs, and Parker Syms.

University of Vermont.—Dr. J. R. Hayden has been appointed lecturer on Venereal Diseases at the University of Vermont.

The Thirty-sixth Anniversary of the Woman's Hospital of this City was held November 19. Speeches were made by Mr. Frederic Coudert, Dr. W. H. Draper, and Mr. John E. Parsons.

Virchow to His Friends.—The following is a translation of the circular note sent by Virchow in acknowledgment of the congratulatory letters and telegrams received by him on the occasion of his birthday:

"The close of the seventieth year of my life has been to my friends an occasion of greater joy than to myself. Age, even when its full burden is not felt, counsels resignation. My friends have nevertheless wished me on this, my birthday, to take a general survey of my past life, my struggles, my work, my successes. They have carried their point.

"From almost every part of the world have come to me the most hearty greetings; from many have come splendid gifts; from not a few, high, even the highest, honors. A whole series of festal days has passed before I have been able even to read all the letters and documents that have been received, or to obtain a realizing sense of the great volume of esteem and attachment which has been poured in upon me. Playmates of my early youth, schoolmates of the student days, fellow-workers from all sides and all lands, even the youngest scholars in the work-shops (Arbeitssaale), have come to me with their words of congratulation.

"It is impossible for me to thank, as I should like, each individual and each association, and to say to them all how happy and honored I feel that so much friendship, so much love, so much kindness, is still left to me, and to say also how earnestly I desire that none of this may be lost to me during the time which yet remains for me to live. May it, therefore, be allowed me to express my feelings in this general letter.

"I will add but one thing more. Let my friends rest assured that their kindly recognition will not spoil my heart, and that I cherish no greater hope than that it will be permitted me to devote all my powers yet for a time in the old way, to the service of science and of humanity.

"RUDOLF VIRCHOW.

"BERLIN, October 25, 1891."

Biliary Lithiasis.—In the interval between the attacks of biliary colic, Dr. Dujardin-Beaumetz prescribes a pill containing euonymin and soap, āā 2 grains, to be taken every night and morning. At the same time, the patient takes immediately after each meal 10 grains of salicylate of sodium. For the relief of the actual attack, from six to seven ounces of olive oil are given in one dose. This often calms the pain. Should it not do so, a hypodermic injection of $\frac{1}{6}$ grain of morphia should be given, combined with $\frac{1}{150}$ grain of atropine.

A Gigantic Infant.—For some reason the maternal pride after a successful accouchement is usually in direct proportion to the weight of the child. On this basis, the proudest mother in Christendom was a Parisian lady, who on January 9th gave birth to a child weighing 11,300 grammes, or about twenty-three pounds.

The Power to Reject Candidates.—An important suit involving the right to reject a candidate for admission to a medical society has terminated in the acquittal of the defendant, who was chairman of a committee on admissions. As previously stated in these columns, Dr. Robert B. Gould brought action against Dr. A. S. Hunter, Chairman of the Committee on Admissions of the Academy of Medicine, for slander as to plaintiff's professional standing, whereby his nomination to the Academy was barred. Although the utterance complained of would be ordinarily privileged as confidential, there was further charge of actual and express malice. The jury not only brought in a verdict for the defendant, as the plaintiff utterly failed to prove his point, but Judge Daly, in view of the groundlessness of the action and of the sacrifice of time and money in defending said action, granted an allowance of four hundred dollars to the defendant's counsel.

The Bicycle and Old Age.—The *Lancet*, in describing a military bicycling trip in which the party made one hundred miles in about ten hours, says in conclusion: The most interesting part of the narrative has still to be told. The veteran cyclist, Major Knox Holmes, at the near close of his eighty-third year, mounted on a tandem with Mr. Males, a young rider under eighteen years of age, accompanied the corps, and arrived at the termination of the expedition five minutes in advance of the rest. He was a little distressed on dismounting, from too hard riding the last few miles, but he soon threw off his fatigue and joined his companions at dinner with thorough zest. His condition is physiologically peculiar. In twelve weeks' new training he has, in the most striking manner, "developed muscle" in the external and the internal vasti, the rectus, and the muscles which form the calf of the leg. It has become so entirely a part of physiological doctrine that after threescore years and ten there is no new development of muscle, that if we had not seen with our own eyes, as we have, this actual development in one whose age exceeds by thirteen years the traditional span of human life, we should have doubted the possibility of its occurrence.

The Next International Medical Congress meets in Rome in 1893, and probably in the last fortnight in September. Professor Baccelli has been elected President, and Professor Maragliano, of Genoa, Secretary. The sections are twelve in number; and, as the results of the various ballots, the following gentlemen have been elected Presidents. Anatomy: Professor Antonelli. Physiology: Professors Albini and Albertoni. Pathology: Professors Bizzozero and Foà. Pharmacology: Professor Cervello. Clinical Medicine: Professors Baccelli, Maragliano, Murri, and Bozzolo. Surgery: Professor Bottini. Obstetrics: Professor Morisani. Psychiatry: Professors Morselli and Tamburini. Ophthalmology: Professors Devincenzi and Secondi. Dermo-Syphilopathy: Professors Campana and Barduzzi. Forensic Medicine: Professor Tamapia. Hygiene: Professors Pagliani, Celli, and Canalis.

The Physique of American Women.—Professor Bowditch has been inquiring into "the Physique of Women in Massachusetts." He has made accurate observations of height, weight, sitting height, and stretch of arms, of over 1,100 women. He found the average height of 1,107 women (without shoes), aged seventeen and upward, to be 158.76 centimetres. Dr. Sargent's average of 1,835 observations, the ages ranging from sixteen to twenty-six, is slightly higher; and Mr. Galton's 770 measurements of English women, from twenty three to fifty-one years of age, give also a higher average. In the latter case the difference may be partly racial, but most of it must be due to the lower ages of some of the American subjects. The average weight of Dr. Bowditch's 1,105 cases, in ordinary in-door clothing, was 56.51 kilogrammes. A comparison with Galton's 276 observations (aged twenty-three to twenty six) shows that the range of weights is greater in the Americans, and also "seems to show that there is little difference between the shortest as well as between the lightest women of the two nationalities, but that the tallest English women surpass the tallest American women in height, while the heaviest American women exceed in weight the heaviest English women." As to sitting height, we need only record that "women appear relatively longer in the body and shorter in the legs than men." Finally, it appears that the popular notion that the arm stretch is equal to the height is much more nearly true for women than for men, Dr. Sargent's measurements giving 100.8 : 100 for the former and 102.8 : 100 for the latter.

Dr. Wm. H. Van Wyck, of this city, died on November 16th. Dr. Van Wyck graduated from Bellevue Medical College in 1865.

The Salts of Strontium, particularly the lactate, are said by Drs. Dujardin-Beaumetz and Paul to diminish albuminuria about one-half.

New Drugs.—In one single number a leading Vienna medical journal manages to rake together the following new remedies: Cocainum hydroiodicum, æthelenum bromatum, ammonium embelicum pulv., methylblue, apocodeinum hydrochloricum, aurum tribromatum, benzanilid, citrarinum puriss, chloral-ammonium, ephedrin pseudo-hydrochloricum, and a new spirit of bryony. Yet it failed to mention dermatol, europhylene, somnal, hypnal, phenocoll, and piperazadine. Vienna journalism is slow.

Bromides and Phthisis.—M. Féré has found that saturating a person or animal with bromides predisposes to tuberculosis.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 15, 1891.

ALFRED L. LOOMIS, M.D., PRESIDENT, IN THE CHAIR.

The Medical and Surgical Treatment of Epilepsy.—The Section on Neurology, under whose auspices the meeting was held, had presented this subject for discussion.

What Can We Expect from the Surgical Treatment of Epilepsy?—DR. B. SACHS read the first paper, with this title. The author said that in a study of the surgical treatment of epilepsy statistics at present were useless. Before attempting to answer the question whether epilepsy was curable by an operation, how to account for failures, whether apparent cures were only temporary or were really due to the operation, he first gave his views of the nature of epilepsy and then related the result in cases operated upon in which he had taken part as neurologist.

Three Classes of Epileptics.—With regard to the nature of epilepsy, he divided the cases into three classes —those due to trauma, those associated with the cerebral palsies of childhood, and idiopathic cases or those due to unknown cause. He saw relatively fewer cases of genuine (idiopathic) epilepsy than during former years. Many of the cases which he at one time would have regarded as idiopathic, he found on closer study to be due to some of the accidents or conditions occurring in early life which had as one result some form of paralysis, the paralysis may have disappeared while the epilepsy remained. In this class and that of traumatic epilepsy there was evidently an anatomical basis for the disease, although the exact nature of this might be a disputed point. It did not prove that so-called idiopathic cases were merely functional, without anatomical basis, because we had not yet found a lesion to account for them. Indeed, he believed there was an anatomical basis for genuine epilepsy, and it was not unlikely improved methods would yet enable us to demonstrate its origin in a sclerotic change in the cortex. Still, on account of the present degree of ignorance on this subject, such cases were, by common consent, regarded as not proper for an operation. The sclerotic process giving rise to the epileptic convulsions were secondary in cases of infantile paralysis being due often to meningeal hemorrhage. As soon as the centre from which the convulsion proceeded became destroyed, the convulsions ceased and paralysis ensued. But the sclerotic change, on the other hand, might not develop for years after the first injury, then giving rise to the epileptic spasm. It might be offered as an objection to this view of the origin of epilepsy that sclerosis had not been determined to exist in cases of traumatic origin, but he thought the fault here lay with the investigator. Where opportunity offered a more careful examination of the cortex should be made in such case.

With this view of the cause of epilepsy, it was clearly the duty of the physician to prevent, if possible, secondary sclerosis, and after it had developed to neutralize its effects. Not knowing the exact conditions under which the sclerosis developed, he could not be expected to meet all the indications for its prevention. Where sclerotic changes had already taken place, causing epilepsy, Victor Horsley, Keen, and others had attempted to excise the affected centres with, in some cases, a satisfactory result; in others, a disappointing one. Where the result was unfavorable, it would seem that other irritable centres had kept up the habit. To make matters worse, excision of a centre meant loss of function or paralysis in the corresponding muscles; so that while one might not by his excision cure the epilepsy, he was very apt to paralyze the parts. Yet in younger persons the function of the excised part ought to be assumed by other parts of the brain. Older persons would have to choose between paralysis or the epilepsy.

Prevent Secondary Sclerosis.—Any organic lesion existing, it should be removed as early as possible in order to prevent the development of secondary sclerosis and of epilepsy. If epilepsy had developed before an operation was performed, it might be assumed that sclerosis had already taken place. Traumatic cases called for immediate surgical interference. Where the skull had sustained a severe, or even a moderate, injury, the surgeon should make an exploration to learn whether there had been an injury to the bone. Even after epilepsy had developed there was still some hope from removing a sensitive scar, lifting depressed bone, or breaking up adhesions, for thereby the epilepsy might be inhibited. But relief had by no means always followed. His own experience covered four cases of traumatic epilepsy, Dr. Wyeth or Dr. Gerster operating; in two there was no improvement, in two, improvement.

Diagnostic Value of the Faradic Current.—In this connection Dr. Sachs mentioned the value of the faradic current applied to the cortex after trephining, in order to determine the exact centres for the group of muscles in which the convulsions started.

The author here passed to the consideration of cases of Jacksonian or focal epilepsy, which could be traced to a lesion occurring either in utero or early childhood, usually of the nature of a cerebral hemorrhage, thrombus, or embolus, leading to softening and secondary sclerotic change in the cortex. About seventy-five per cent. of children with cerebral paralyses developed epilepsy. He had had three cases of this kind operated upon, the cortex in only one being incised, in that instance incisions being made into it but no excision practised. There had been improvement in all, though they were only comparatively recent cases.

In conclusion, he said that the surgeon might be able to cure a few cases of epilepsy; he might be able to improve many; but he and the neurologist should in the future work together to prevent the development of epilepsy, if possible.

The Medical Treatment of Epilepsy.—DR. C. L. DANA said he would not speak of the treatment of epilepsy in the usual way, as this had been done very thoroughly by Dr. Seguin on a recent occasion: He would speak of the subject rather from the basis of diagnosis and prognosis. He regarded the larger proportion of cases of epilepsy as the expression of a degenerative disease. Idiopathic epilepsy was symptomatic, not of any special focal lesion or organic change, but expressive of a family or individual degenerative tendency. In the idiopathic cases would be found certain physical, physiological, and psychical marks by which one could recognize the intensity of this degenerative process. Therefore, before undertaking either medical or surgical treatment, one should make a most careful examination of the patient with a view to determining to what extent this stigmata of degeneration was present. In proportion to the intensity of this stigmata would treatment prove of little avail. Epileptics showed in varying degree the following signs of a degenerative tendency: Want of robustness; asymmetry of the cranium, present in seventy per cent. of the cases; the asymmetry was not usually very marked. In a certain proportion of cases there was shortening of the parietal arch; in another proportion, of the frontal arch, especially in petit mal; in women a high and protruding forehead was thought by Benedik to indicate, perhaps not epileptic tendency, but convulsive tendency. Further indications of the epileptic stigmata: The teeth badly set in the jaws; the palatal arch sharply arched in many cases; the face asymmetrical and uncultivated; in voluntary movements there was manifest unequal innervation; difference in the pupillary margins, astigmatism in many cases; deformity of the ears in many cases; low vital capacity; genital anomalies were common; pecu-

liarities in the fingers and hands. The asymmetry of the head might show itself either in the cranium or face, or both; if in the face it was usually of the upper portion.

Physiological Stigmata.—Among these were facial twitchings, stammering, nystagmus, anomalies of the sexual instinct, irresistible impulses, the muscular power below normal, peculiarities in standing and gait, relatively less secretion of phosphoric acid compared with urea, often anæsthesia and defects of special senses.

Psychical Stigmata.—These, he said, were too well known to require more than mere mention. There was the tendency to mental aberration, moral depreciation, waywardness, lack of will-power, sexual aberrations.

The question of continuance of medical treatment, or urging it, or of interfering surgically, would depend largely upon the intensity of these stigmata or evidences of degeneration. He believed there was only a minority of epileptics who should be kept upon bromides. He placed importance upon mental occupation, upon hygiene and diet, placing these above medical treatment. Baths and bromides constituted the main features of treatment in certain European institutions. If there was a sclerotic change, as seemed probable, it furnished a basis, he thought, for continuance of the old method of treatment by nitrate of silver, and for the present use of arsenic. He thought a small amount of nitrate of silver and arsenic useful adjuncts to other treatment. He also gave some phosphoric acid at intervals between bromide treatment. Hydrate of chloral was a useful adjunct of bromides, and lately he had tried chloralamid with considerable satisfaction. Antipyrine might prove useful, and had been advocated by Dr. Wood. Bromide of gold acted only in improving nutrition and increasing the bodily weight. Bromide of camphor was of well established value in petit mal. He had faith in the continued use of the galvanic current to the brain and neck, but time hardly permitted of its thorough application by the physician. There were many other drugs used more or less in epilepsy, but they were not of sufficient value to warrant taking up the time of the Society.

The Surgeon's View.—Dr. John A. Wyeth said that the older he grew the more he became convinced of the value of co-operation between the medical and the surgical mind, especially in the field of brain surgery. His remarks referred mainly to the methods of exposing the brain in epilepsy. There were three, all of which were about equally good. The one was by trephining—taking out successive buttons of bone; this method had become popular, it permitted replacing the pieces. In the second method the bone was cut away, the particles being cast away, although they could be replaced. The third method he had made use of considerably the past year and a half. It consisted in making a large horseshoe-shaped incision down to the bone and through it, not dissecting the scalp off the bone. Thus a trap-door was made which was turned down over the face, exposing the dura. Owing to the line of incision through the bone having been somewhat large, an eighth to a quarter of an inch, union had been cicatricial, not bony; but he believed that with improved instruments he would be enabled to leave a separation of only one-sixteenth of an inch, and in that event bony union could be expected. In some of his cases there had been elevation of the bone-flap. He believed there were more cases of epilepsy amenable to surgical treatment than physicians supposed. He thought that simple exposure of the brain could not be classed among serious operations.

Dangers of Operative Procedures.—Dr. W. R. Birdsall said that while he was pleased to hear Dr. Wyeth's opinion as to the safety of operating in epilepsy, he yet could not forget the fact that cases did die as a result of an operation in the hands of those believed to be competent surgeons. Every now and then some defect in the antiseptic method, or other condition, was accountable for a death. In a case of brain tumor, for instance, the risk might well be taken. In one case he had advised rather against an operation, it being one of epilepsy developing recently, or about the twentieth year, in a girl who had a slight depression of the skull when six months of age. The convulsions became almost immediately general, and there was less development of the body on the side opposite the cranial lesion, leading him to believe there was cortical change and arrest of development of the motor areas, and that therefore an operation would probably prove useless. He thought it was too early to speak much for or against the operation. Evidently it was best to resort to it early if it were indicated. Among drugs, none equalled bromides. He did not think electricity was very promising. It was well to remember Esquirol's observation that a change in treatment was likely to result for a time in some improvement. Various surgical measures had been proposed and practised, such as blood-letting, tying the carotid, castration, etc. It was hard to say how much the improvement (temporary) was due to the change in treatment and to mental shock. This remark applied also to trephining, which was apt to diminish the attacks only for a time.

Dr. M. Allen Starr thought the mental effect of any new procedure in these cases handicapped very much judgment of its value. There was no field in which the physician could more appropriately show some wholesome scepticism. As bearing on this aspect of the case he called attention to an article by Professor White, of Philadelphia, upon the therapeutic effects of operations *per se*. It showed that many cases of epilepsy might be improved for a year or more by trephining and then relapse. It appeared that the mental effect of any procedure in epileptics was almost as important as in hysteria.

He fully approved of Dr. Sachs's statement that cases should be selected, and that operations should be limited to cases of traumatic epilepsy, and those in which the brain lesion could be located, but the trouble was that ninety nine cases out of a hundred of epileptics were not traumatic. About ninety-nine cases out of a hundred were idiopathic, whose origin we knew nothing of.

He knew of two cases in which everything pointed to the propriety of an operation; the patients went into the operating-room well, except for an occasional fit, they were operated upon by one of the ablest surgeons in one of the best hospitals, and they died within five hours after the operation. The skull in these cases was found to be very thick.

Failures.—Dr. Starr had had the supervision of an operation in three traumatic cases the past year, in which there was apparently a direct connection between the blow upon the head and the muscular spasm; the surgeons admitted the propriety of an operation, yet at the end of nineteen months in one, fifteen in another, fourteen in the other, no apparent good had come from the operation whatever. In one or two there was evidence of old fracture beneath the incision, in one a depression outside, none of the inner table. The brain was exposed in all. The improvement had been in all only temporary. He confessed to not having yet had enough courage to advise a surgeon to excise a part of the cortex of the brain. If sclerotic tissue was present, and could not be seen, it probably did not equal that which would follow excision. Looking, therefore, at the future of the surgery of epilepsy, he thought there was not the brilliant prospect which there seemed to be two or three years ago. We would have to proceed with a great deal of care.

Regarding the medicinal treatment, he, of course, depended most upon bromides; but he called attention to an article by Haig, published in *Brain*, for June, on the influence of digestive processes upon the treatment of fits, in which the author claimed that, by observing the quantity of uric acid in the urine and blood, he could predict an attack of epilepsy in the epileptic, and on these studies he based the indications for diet, etc.

Hemiplegia and Epilepsy.—Dr. E. D. Fisher said he had been giving some attention to epilepsy in cases in which, during childhood, there had been hemiplegia.

Most of the cases which he had seen were in adults, and he was unable to find much difference between the convulsions in these cases and in idiopathic cases; the convulsion began no more frequently on the paretic side. Perhaps it had been different in childhood.

As was well known, post mortem examination sometimes showed atrophy of the convolutions in some cases, and he thought that if an operation had been performed early, say at the age of three or four years, this progressive atrophic change might have been checked, nutrition encouraged, and the embryonic cells enabled, by the increased nutrition and education, to take on more or less their normal function. This was important, not alone from the stand-point of overcoming the epilepsy, but also of improving the mental condition, which in these cases was well known to be deficient.

No Epileptic Stigmata.—Dr. Fisher thought the defects or stigmata named by Dr. Dana did not belong to epileptics except those of the idiotic class. He had reached this conclusion after observation of many cases.

Cure by Mental Shock.—Dr. Græme M. Hammond, Chairman of the Section, said of mental shock or mental impression as a cure of epilepsy or prevention of the attack, that in institutions nurses and attendants used this means for aborting a threatened attack; and that one young man was cured of severe epilepsy, lasting perhaps two years, brought on during participation in a walking-match, by the nervous shock experienced on the cylinder head of an elevated-train engine falling down by him. He also knew of two patients who had come to his clinic for treatment for epilepsy who claimed afterward to have been cured by hypnotism.

Dr. Sachs said, in closing the discussion, that he could not agree with Dr. Starr as to the proportion of idiopathic cases. He did not believe it was anything like even ninety per cent. The closer we analyzed our cases, the fewer would appear the idiopathic kind or those in which there was no evident organic change.

Regarding the danger of an operation, he thought surgeons ought to be able to promise that the operation at least would not endanger life in adults. In children it was different, as they did not tolerate cerebral operations well. He had had four cases of microcephalus operated upon in children and three had died. Those were the only deaths from cerebral operations which he had seen.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Fourth Annual Meeting, held at Richmond, Va., November 10, 11, *and* 12, 1891.

Lewis S. McMurtry, M.D., of Louisville, President.

First Day, Tuesday, November 10th.

Albuminuria: Its Relation to Surgical Operations.—Dr. J. W. Long, of Randleman, N. C., considered this subject under the following heads: 1. Does an operation ever induce albuminuria in healthy kidneys, *a*, by the anæsthetic employed; *b*, by the operation, *per se*? 2. Does albuminuria increase the dangers of anæsthesia, *a*, by the anæsthetic employed; *b*, by the operation itself? 3. Does the operation ever relieve albuminuria?

His conclusions were: 1. That neither ether nor chloroform injured the healthy kidneys. 2. When real disturbance from the use of the anæsthetic occurred, the kidneys being perfectly healthy, it was due rather to the prolonged narcosis and exposure of the patient, or to perhaps the combined influence of the operation and anæsthetic. 3. That a mild degree of albuminuria and nephritis did not contraindicate the use of chloroform or of ether. 4. Even in the presence of advanced renal changes an anæsthetic might be used, provided the family were advised of the additional risk. 5. Of the two anæsthetics, it was generally thought that ether was the safest, unless in obstetric operations. 6. Where albuminuria followed an operation, it might be due in part to the operation, in part to the anæsthetic. 7. The cause here was either reflex or sepsis. 8. That operations on the abdominal and genito-urinary organs and rectum were especially liable to produce renal complications. 9. That a healthy condition of the kidneys minimized, but did not obviate entirely, the dangers referred to. 10. Albuminuria was always indicative of renal lesion and should be regarded with anxiety, but it was not a positive contraindication to an operation. 11. When albuminuria was associated with other evidences of advanced renal changes, no operation should be undertaken without stating the dangers incident to the kidneys. 12. Albuminuria sometimes disappeared after an operation. 13. An operation should never be undertaken without thorough investigation of the kidneys.

Dr. W. W. Potter, of Buffalo, opened the discussion, and said that in healthy subjects he thought one could safely use chloroform. He had employed chloroform in at least three thousand cases, and in none had there been a death from this agent. He strongly impressed the necessity for an expert to administer the anæsthetic.

Dr. Baxter, of Chattanooga, said he had repeatedly seen albuminuria after shock from accidents, and he believed in operations this was frequently the cause, rather than the anæsthetic.

Dr. Davis, in experiments on dogs, had seen anæsthesia frequently produce suppression of urine. He expressed preference for chloroform, and, like other speakers, impressed the need of care in its administration by an experienced man.

Dr. Hunter McGuire, of Richmond, had most frequently used chloroform, yet he thought ether was sometimes indicated. Judgment was required in the selection of the anæsthetic. He did not place any reliance on statistics showing a much larger percentage of deaths from chloroform, in proportion to the number of patients anæsthetized, than from ether.

Dr. Westmoreland, of Atlanta, thought albumin in the urine, of great or little amount, of no special significance unless the microscope showed renal casts. Unless such microscopic evidence of renal disease was present, albuminuria did not contraindicate the use of an anæsthetic.

Dr. C. Rollock, of Cheraw, S. C., had used chloroform nearly altogether, without a death; he had used ether about two hundred times, with two deaths attributable to the anæsthetic. He preceded the administration of the anæsthetic by giving brandy well diluted with water, and thus kept up the heart's action.

Dr. Joseph Price, of Philadelphia, said it was sometimes difficult to say whether death were due to the operation or to the anæsthetic, yet he was convinced from observation of many cases operated upon in different hospitals that the anæsthetic was often at fault. It might be said that some patients died of chronic surgery—operation lasting, for instance, an hour, or an hour and a half. He did not doubt that some men, without disease of the kidneys or other organs, would succumb to ether if administered as long as it was in some operations, even though there were no surgical interference.

Dr. Albert Vander Veer, of Albany, had seen death from chloroform, never from ether. He thought there must be an organic change to account for it, although we we might not be able to see it. He did not hesitate to give chloroform to children. He preceded it by $\frac{1}{100}$ gr. of atropin, and $\frac{1}{8}$ gr. of morphine introduced hypodermatically.

Dr. H. P. C. Wilson, of Baltimore, had used chloroform for over forty years, and had not seen a death from it. The profession here seemed to look upon death from ether as all right, and death from chloroform as all wrong.

After some further discussion Dr. Long closed by saying that, while he would not deny there might be a func-

tional albuminuria, yet this could not long continue without an organic lesion taking place.

Systemic Infection from Gonorrhœa.—Dr. Bedford Brown, of Alexandria, Va., read the paper. Five cases were related in exposition of the text. Gonorrhœa was not an innocent disease, as was commonly supposed. It might extend over the entire genito-urinary system, or where there was continuity of the epithelial lining. But its spread was not limited to these channels; in some cases the entrance was through the lymphatics, and the limitation only the general system. Where the poison extended by continuity of the epithelial surface it was essentially pus-producing; where it was absorbed through the lymphatics, the local lesions were rarely pus-producing.

The first case was of the first variety, in a male, the gonorrhœal inflammation extending from the urethra to the prostate, to the bladder, the ureter, the pelvis, and body of one kidney, the kidney breaking down in abscess, escape of the pus and *débris* of the organ in the urine, final recovery of the patient with but one kidney. The extension of the disease along the ureter, in this and the next case, was accompanied by severe pain in the corresponding region.

The second case occurred in a female, who had gonorrhœal urethritis, cystitis, double ureteritis; then the urine became scanty, contained albumin and casts; the case ended in uræmic convulsions and death. He believed more cases of chronic nephritis were due to gonorrhœa than was commonly supposed.

In the third case the poison extended by the lymphatics; first the inguinal glands became enlarged, later those of the thigh, etc.; then a phlebitis and an orchitis. This patient finally recovered.

In the fourth case, three weeks following gonorrhœal urethritis, there developed gonorrhœal synovitis in both ankles and knees, then violent lymphadenitis in both inguinal regions, septic endocarditis, deep-seated pain in the eye without conjunctivitis. The gonorrhœal microbe here was carried, he thought, to the globe of the eye through the systemic circulation.

The fifth case was one of gonorrhœal septicæmia, with death in coma.

Dr. Robert T. Morris, of New York, in discussing this paper, said the conditions mentioned in the paper as occurring in gonorrhœa undoubtedly did occur more frequently than one would suppose from reading the books. Few authorities gave anything like a fair description of the cases. He did not suppose the gonococcus of Neiser caused the suppuration, but that it was followed by others which did have that effect. The speaker regarded the cases as those of gonorrhœal septicæmia. He spoke of the value of peroxide of hydrogen, introduced into the bladder, as a means of controlling the cystitis.

Dr. Joseph Price remarked on the great frequency of gonorrhœas, their treatment almost exclusively, not by physicians, but at drug-stores, nearly all of which were "clap-traps." A person with gonorrhœa or syphilis might better be locked up than a murderer, as he was likely to do infinitely more mischief to the community. Some years ago he had charge of a venereal clinic in Philadelphia, and the number of men who came there for treatment was surprisingly large. He could say safely, not fewer than one hundred women, wives of men whom he had previously known to suffer from gonorrhœa, had come to him and submitted to an operation for resulting pelvic disease. He had seen cases like those described by Dr. Brown, and he thought it might be well if the frightful results of venereal disease were described in print, and placed on the table where every young man could read.

Dr. Baxter thought the fact that so many of the wives suffered subsequently from pelvic trouble was evidence that the men had not been cured of the gonorrhœa before their marriage. He did not believe urethral stricture could be cured by internal medication.

Dr. J. D. S. Davis had had a case of gonorrhœa in a young man, followed by gonorrhœal rheumatism. During another attack he begged to have something done to prevent recurrence of the rheumatic complication. He decided to effect thorough cleansing of the urethra by repeated flushings, and for this purpose made puncture over the pubes with a large trocar, through which the injections were made. The patient escaped the rheumatic complication. He had pursued the same course in another case, at the solicitation of the patient, with a similar result.

Some Additional Cases of External Perineal Urethrotomy without a Guide.—Dr. Edwin Michael, of Baltimore, in this paper reported, in addition to those described in a former communication, eight more cases of external perineal urethrotomy without a guide, the cause of the obstruction being, in about equal proportion, gonorrhœal stricture and traumatic stricture. The results had been very satisfactory, due, he thought, not to any special method of operating, but to following aseptic principles—making free incision, establishing free drainage, and enforcing cleanliness. The course pursued was to cut down through the perineal structures until the urethra was reached, which was usually entered posterior to the stricture, sometimes anteriorly, and the stricture then overcome. In one of the traumatic cases in which the cicatricial tissue was marked and the urethra deflexed, he saved time and cutting by passing an instrument from the direction of the bladder after making a supra-pubic opening.

The discussion brought out an expression of opinion on the propriety of supra-pubic puncture of the bladder. It was condemned generally by Drs. Hunter McGuire and Joseph Price.

Drs. Rollock, Long, Michael, and the two Davises, thought there were conditions justifying puncture, and the under operation, done with care, was almost without danger.

Reduction of Dislocations by Manipulation.—Dr. W. F. Westmoreland, of Atlanta, advocated, in a paper of this title, the reduction of dislocations, wherever possible, by manipulation instead of by extension and rotation, in order to avoid any injury which sometimes arose from the force required in carrying out the latter method. Of course in some joints reduction by manipulation was impossible.

In the first part of his remarks he mentioned two cases of dislocation of the hyoid bone which had come under his observation, in one of which there had been a previous dislocation, in the other dislocation five times previously. He believed the accident was of much more common occurrence than had been stated in the books. The true condition was apt to be overlooked, and the patient treated by gargles, etc., for some throat difficulty. Replacement usually took place spontaneously, when the patient gagged and threw the head forward. He had been able to find only six recorded cases.

The speaker next took up shoulder dislocation, more particularly the subcoracoid variety, which he regarded as most frequent. He felt sure that all the cases seen by him in the past, and then supposed to be subglenoid, were really subcoracoid. The method of reduction which he had practised in a very considerable number of cases, with great satisfaction, was called Kocher's. It was unaccompanied by the use of force, and consequently did not cause pain and injury to the structures of the joint. Where there was a rent in the lower portion of the capsule somewhat different manipulation would be required. The forearm bent on the arm, the elbow held against the body, elevate it slightly, make rotation outward by simple circumduction. The same manipulation would be successful where the bone was caught between the muscles. He was confident one could reduce any forward dislocation of the humerus by Kocher's method. But if the coracoid ligament were ruptured, he did not think manipulation would succeed as a rule. The reduction by this

method of manipulation depended upon putting the coracoid ligament upon the stretch and using it as a lever. When it was torn the procedure would fail.

Complications in Pelvic Surgery, and how to Deal with Them.—Dr. Joseph Price, of Philadelphia, presented in illustration of the text several specimens and diagrams of recent cases. He distinguished between abdominal and pelvic surgery, and showed that the general surgeon was likely to get into a tangle on dealing with extensive adhesions, etc. It appeared in the course of the paper that the author laid stress on cleavage, as opposed to tearing and cutting, where there were extensive adhesions; on the use of hot water where there was much hemorrhage and manipulation, the effect of hot water being not only to control bleeding, but also to overcome shock; the use of the drainage-tube in certain cases; on maintaining the integrity of the bowel, the use of vaginal drainage in certain conditions, etc.

Dr. Opie, of Baltimore, thought there should be no use for the drainage-tube when the operation had been done aseptically.

Dr. H. O. Marcy, of Boston, thought the drainage-tube should be used only for a definite purpose, namely, where there was a suspicion of infection, and where fluids required to be removed.

Dr. Kollock, of South Carolina, had seen cases of pus-tubes in which there was no cellulitis, but had hardly dared assert the fact in face of the contrary view being so generally entertained until now.

Dr. Price related a similar observation. He had never been able to find cellulitis in any case of pyosalpinx.

Dr. Albert Vander Veer, of Albany, thought the drainage-tube when used was also of great value in giving early alarm in case of hemorrhage. Like the author, he spoke against the use of the aspirating needle because of the attendant dangers. He regarded it of importance to replace the pelvic organs at the conclusion of the operation in their normal position. Rearrange the gut, mesentery, and especially the omentum, and there would be less liability to dangerous adhesions.

In closing the discussion, Dr. Price said he thought there was not more than one case in about five hundred where the adhesions could not be overcome and the operation completed. The greater one's experience, and therefore skill, the fewer of his laparotomies would prove simply exploratory.

Laparotomies Performed during the Past Year.—Dr. Thomas Opie, of Boston, in this paper tabulated thirty-two laparotomies which he had performed at the Baltimore City Hospital the past year. Much more could be learned from a report of all cases than of a series of cases, as in the latter event they were likely to be selected ones. His 32 cases were divided as followed: ovarian tumor in 6, chronic ovaritis in 7; fibroid tumors in 4; hydrosalpinx in 5; retroflexion, dysmenorrhœa, etc., in 3; exploratory incision in 3; extra-uterine pregnancy in 1; cyst of the broad ligament in 1; cystic degeneration of the ovary in 1. The deaths were: in oöphorectomy for pyosalpinx, 1; shock in ovariotomy, 1; abdominal hysterectomy for fibroid tumor, 1; colloid cyst, 1; in all, 4. The details of conditions leading up to death in these cases were given. Stitch abscess occurred nine times. He believed the time had about arrived when the drainage tube should be dispensed with. He also thought there was too much flushing of the abdomen. Did it not damage the epithelium of the peritoneum and disable it for combating germs, etc.? He thought sponging out of fluid safer. Nature sealed the opening aseptically in less than twenty-four hours, and the surgeon should aid this result.

Drs. Johnson, W. E. B. Davis, Price, and others, defended the use of the drainage-tube under certain conditions. Dr. Davis said the trouble which had followed its use was due largely to leaving it in too long. It could remain quite safely twelve to fourteen hours. They disapproved of the use of sponging in the place of flushing.

Dr. H. P. C. Wilson had been unable to trace pyosalpinx to gonorrhœa, although he had treated a number of women for gonorrhœa contracted from the husband. He had removed the uterine appendages in four or five cases of mania, with the result of curing the mental trouble.

Dr. Price was glad to hear the experience of Dr. Wilson, since it harmonized with his own. He had repeatedly seen girls and women who had been laboring under mental depression, taking no interest in any of the affairs of life, having convulsions during the menstrual period, become happy and healthy after a pelvic operation.

Obscure Origin of Ovarian Cystoma.—Dr. C. Kollock, of South Carolina, the author, first reviewed the theories which had been advanced in explanation of the development of ovarian cystoma, and said that although some of them were more or less plausible, yet the true cause had not yet been found.

Congestion recurring at the menstrual period, scrofulous, tubercular, or other diathesis, marriage, sterility, and other theories in explanation of the cystic degeneration, could not apply in three cases which had come under his observation. The three cases were in unmarried women, one in the twenties, one seventeen, the other only twelve. The influence of abnormal menstruation, of inherited tendency, of disease of any other nature, of diathesis, of desire to marry, of restrained sexual appetite, etc., could safely be excluded as an etiological factor.

OUR LONDON LETTER.

(From our Special Correspondent.)

FIFTY CASES OF INGUINAL COLOTOMY—HOW TO DIAGNOSE INNOCENT FROM MALIGNANT STRICTURES—LESIONS OF SPINAL NERVE-ROOTS FROM SECONDARY CARCINOMATOUS GROWTHS—URIC ACID AS A CAUSE OF HIGH ARTERIAL TENSION—AN EXPERIMENTAL STUDY OF DIGESTION AFTER GASTROSTOMY—LAMINECTOMY FOR PARAPLEGIA—THE COMING ELECTION TO THE MEDICAL COUNCIL.

London, October 31, 1891.

At the Medical Society of London, on Monday evening last, Mr. Harrison Cripps gave an account of two cases of stricture of the colon which had been diagnosed by laparotomy and treated by colotomy. Mr. Herbert Allingham then read notes of his first fifty cases of left inguinal colotomy. Mr. Allingham remarked that for practical purposes the mesentery might be described as long, medium, or short; this division was of importance in reference to the possibility of making a spur, and the cause of after-prolapse of the bowel. Only two of the cases died from the operation, and in both instances from accidental causes. In 36 of the cases the ordinary inguinal operation was performed; in 14, the supplementary operation. In 17 of the 50 the mesentery was long, in 25 of medium length, and in 8 short. In 9 there was no spur. In 17 prolapse took place—from the upper end only in 5 cases, from the lower end only in 6 cases, and from both ends in 6 cases. The gut was twisted when forced up, so that the bowels acted from the lower of the two openings in 7 out of the 50 cases.

Mr. Jessett thought it was a waste of time to stitch the peritoneum to the skin, and that it weakened the abdominal walls and rendered prolapse more probable.

Mr. Goodsall said inguinal colotomy was far preferable to the lumbar operation, if only because the patient was independent of outside help in relieving the bowel. He observed that in men upward of eighty per cent. of strictures were malignant, while in women not more than twenty per cent. were cancerous. The behavior of the bowels was a guide in diagnosing malignant from inno-

cent strictures. In the latter the desire to empty the bowel was felt at certain times only, whereas in malignant strictures it occurred at any time. Non-malignant strictures he had found almost invariably secondary to puerperal mischief.

Mr. Bruce Clarke insisted on the importance of trying to get the spur as low as possible.

At the Medical and Chirurgical Society's meeting, on Tuesday last, the first communication read was one by Mr. Raymond Johnson and Dr. George Murray. The authors described the case of a patient who had died from multiple secondary carcinomatous growths consequent upon a primary growth in the breast. The symptom especially considered was the paralysis of certain muscles of the upper limb; after death these were found to be pale and atrophied. The lesion of the anterior nerve-roots, caused by the secondary growth in the dura mater, was of almost experimental accuracy; it extended from the sixth cervical root above to the third dorsal root below. The authors compared the muscles found atrophied in this case and those found to be supplied by the same nerve roots in the monkey by the researches of Ferrier and Yeo. They confirmed the observation made by Dr. Beevor concerning the double origin of the nerve-supply of the pectoralis major; the sternal and costal fibres of this muscle were atrophied, while the clavicular fibres remained unaffected, and were thus shown to be supplied by nerve-fibres derived above the sixth cervical root.

Dr. Haig then read a paper on "Uric Acid as a Cause of High Arterial Tension and its Consequences." This was a continuation of the author's former paper on the subject. He maintained that, other things being equal, arterial tension varied directly with the amount of uric acid in the blood; and that opium, mercury, and other drugs probably affected arterial tension by their action on uric acid. He had reached this conclusion from an experimental investigation of the uric-acid headache (migraine). He believed that opium cleared the blood of uric acid by storing it in the tissues—not by eliminating it; when the stored uric acid was again in solution in the blood the uric acid rebound came, with all the signs of excess of uric acid in the circulation. The effects of opium on the brain and skin were due to its influence on uric acid. Uric acid, by contracting the arterioles and capillaries, raised the tension, and slowed the heart in accordance with Marey's law of pulse-rate. It might also produce irregularity or intermission of the pulse, and secondary effects, such as syncope, angina, or cerebral hemorrhage. These secondary effects were most likely to be met with at the hours when the amount of uric acid in the blood was naturally greatest, and many functional disturbances due to uric acid were worst at these hours. The author mentioned the parallel action of digitalis and erythrophleum, and referred to Professor Reigel's paper on bradycardia. He said a knowledge of the effects of uric acid on the rate of the pulse should give an explanation of most of the causes of bradycardia in the most simple manner. In concluding his paper he maintained that the vascular effects of uric acid might influence every tissue and structure of the body.

Dr. Haig's views did not apparently find much support among his hearers. Dr. Herringham said he had endeavored to corroborate Dr. Haig's researches, but without success. He thought Haycraft's process was unreliable, and Dr. Haig had used this method to estimate the uric acid. Dr. Hunter acknowledged the laboriousness of Dr. Haig's researches, but thought he was trying to establish too important a *rôle* for uric acid in disease.

At the last meeting of the Clinical Society Dr. Handford gave an interesting account of an experimental investigation of the movements and of the contents of the stomach which had been made on a patient on whom gastrostomy had been performed. The operation was performed at the end of May, 1890, for stricture of the œsophagus, which was found at the necropsy to be carcinomatous in nature. The patient survived the operation one hundred and ninety three days. He used to take six meals in the twenty-four hours, consisting of eight and a half pints of fluid (milk and water), two ounces of bread-crumb, four ounces of pounded, uncooked meat, five ounces of cream, and three eggs, with an ounce of brandy. No evidence could be obtained of peristaltic movements of the stomach walls, which appeared to have been quite checked by the adhesions of the stomach to the abdominal parietes. Digestion took place efficiently in the complete absence of peristaltic movements of the stomach itself, but both the diaphragm and the heart seemed to have influence in preventing stagnation of the fluid contents of the stomach. The history of the case showed that a considerable gain in weight was not incompatible with the presence of advanced malignant disease, and that a diet largely fluid could be maintained for months without producing indigestion. The rapid introduction of large quantities of food into the stomach, the absence of pleasure in eating and of the perception of flavors were not incompatible with very perfect digestion and active nutrition. Given a suitable diet, fine division of it appeared to be the most important factor in determining rapid and easy digestion. Hydrochloric acid was absent till two hours or more after a meal, but lactic acid was found in the stomach in abundance as early as half an hour after taking a full meal. Lactic acid appeared to be more abundantly and quickly produced from bread and from beef-tea; less quickly from milk. The highest total acidity was generally after the meat meal. The total acidity steadily increased from half an hour after a meal, when it averaged 0.085 up to three hours, when it reached 0.63, and was then chiefly due to hydrochloric acid. But at this period the absolute quantity of fluid was generally small—an important point to remember in estimating the quantity of alkali required for neutralization. The sugar all disappeared within two hours after food was taken. It was formed from beef tea and bread, when, so far as could be learned, no ptyalin or diastase was present. It was, therefore, a question whether starch might not be changed into dextrine and grape-sugar under the influence of micro-organisms and the body temperature.

A short discussion ensued. Mr. Symonds and the President (Sir Dyce Duckworth) thought treatment by tubage should be employed before performing gastrostomy. Mr. Symonds remarked that many patients, if put in bed and treated with opium and nutrient enemata, had the power to swallow restored to some extent. Dr. L. E. Shaw mentioned a case in Guy's Hospital in which, after the first stage of gastrostomy had been performed, the patient became able to swallow, and did so until death, weeks afterward.

Mr. W. Arbuthnot Lane then gave an account of eleven cases in which he performed laminectomy for compression paraplegia resulting from spinal caries. He thought operative interference in such cases involved very slight risk. It was followed by very little pain, it relieved the patient of the compression symptoms, and it enabled one to treat the diseased vertebræ directly—not only by spooning, irrigation, and the thorough removal of all carious material and diseased bone, but also by the repeated local application of iodoform, from which Mr. Lane had obtained excellent results.

The re-election of Direct Representatives to the General Medical Council is now drawing near. The three members for England and Wales are not, it appears, to be returned unopposed, as two fresh candidates—Dr. Alderson and Mr. George Brown—offer themselves, who claim support on the ground of their being general practitioners and thus more in touch with the general body of the profession.

A Death from Cocaine.—A young physician in Bournemouth, England, died recently from the effects of cocaine which he had applied too freely to an aching tooth.

MATERNAL IMPRESSIONS.

To the Editor of the Medical Record.

Sir: The series of anecdotes which have been running through the columns of the Medical Record lately have a very familiar sound. I am continually reminded of the more or less harrowing recitals with which old ladies, gathered about the kitchen-fire, are apt to beguile the tedium of the first stage of labor. Unlike your correspondent, "Physician," I am a confirmed sceptic on the subject of maternal impressions. It seems to me the height of absurdity to attribute to this cause all the defects and deformities of children. It is reasonably held that convolutions of the cord may so ligate a limb as to cause its amputation in utero. I know a young lady born with only one hand, but this could not be traced to any maternal impression. It seems a remnant of past superstitions to be continually magnifying mere coincidences into cases. If it were true, as "Physician" concludes, that a mother could make her child an idiot through anger at her pregnancy, this land would be filled with idiots. I could give case after case to prove this point, but let a single one suffice. Mrs. M—— found herself in the unwelcome condition of pregnancy, and among other fruitless expedients for relief took an enormous dose of strong decoction of tansy, and was taken up in convulsions. Nevertheless, at full term, she was delivered of a healthy, well-formed, and intelligent girl.

A single case, also, bearing on deformities.

Mrs. A——, while carrying her child, lost three fingers and part of a thumb by the accidental discharge of a revolver. She was greatly shocked, and feeling sure her unborn infant would be similarly disfigured, hoped for its death. When the child was born she refused to look at it, so strong was her faith in the maternal-impression theory. But I was able to turn the laugh on the wise women assembled, by showing them a fat, ten-pound girl, without a mark on its fair flesh.

Dr. Rachel Gleason relates the case of a lady medical student, who, in the early months of her pregnancy, was punctually at her place in the dissecting room, most efficient at clinics, yet bore a beautiful child free from any blemish. A richer field of horrors for maternal impressions could scarcely be imagined.

Will "Physician" please tell us the cause of the double-headed boy reported in the Record of November 7th? Can he account on the theory of maternal impressions for double-headed and six legged calves in the spring? Perhaps spots on apples and nubbins on potatoes will yet be satisfactorily explained in the same light. Seriously, while the vast majority of cases clearly point the other way, does common sense, let alone science, sustain a nineteenth-century physician in pinning his faith to maternal impressions because of a few isolated, albeit striking, coincidences.

E. S. Rich, M.D.

Kennedy, N. Y.

METHYL-BLUE IN ACUTE GONORRHŒA.

To the Editor of the Medical Record.

Sir: At the meeting of German Physicians of New York, of February 27, 1891, I demonstrated (with specimens) that the urine of persons taking methyl-blue, in doses of 0.2 (3⅓ grains), two or three times daily, remain undecomposed, even if kept in an uncovered vessel, at ordinary temperature, for several weeks. Inoculations made with some of this dyed urine on bouillon-gelatine did not develop any colonies. This fact seemed to justify the trial of methyl blue in all the disorders of the genito-urinary system which are caused by micro organisms. At the March meeting of the above-named Society I showed that the urine of one patient with pyelitis, and of two other patients with acute gonorrhœa, remained aseptic after having taken methyl-blue internally, and that inoculations made with it on bouillon-gelatine and agar-agar did not develop any colonies of micro-organisms. This was the reason which led me to apply methyl blue in acute gonorrhœa.

Twelve patients of the German Dispensary, with acute gonorrhœa, were treated in no other way than by administering internally 0.2 methyl blue, in a gelatine capsule, once a day, after supper; nearly all of them lost the burning pains in the penis they had had the next day. Of these twelve patients nine have been completely cured within eight to thirty-five days (one each in eight, twelve, thirteen, and sixteen days; the other five in from three to five weeks). Among the remaining three, one derived no benefit whatever from the methyl blue; in the two others the pain became lessened but the flow did not seem to become altered by this mode of treatment, and here use was made of the usual mode of treatment by injections.

I would like here to state that although I have brought up the subject of methyl-blue before the above-named Society, and mentioned the apparent rationality of its use in diseases of the genito-urinary organs, Dr. I. Adler was the first to apply methyl-blue in gonorrhœa, by injecting solutions of this substance, whereas I have applied it internally only.

My letter, Mr. Editor, would grow too long were I to mention all the trials I have made with methyl-blue; still, I should like to call attention to a few interesting facts with reference to the use of it.

A patient with œdema and anasarca, dependent upon a chronic nephritis, lost his œdema in eight days, having taken 3⅓ grains methyl-blue *pro die;* he returned after six months with the same symptoms, having been free from them meanwhile; he again resumed the treatment with methyl-blue, and the œdema disappeared in eight days.

In one case of herpes zoster, treated with methyl-blue, 0.2 internally once a day, and no other medication whatever, the pain disappeared in two days, and the herpes-vesicles dried up on the seventh day. (This patient was presented as cured at the last meeting of the German Medical Society, November 2, 1891.)

One case with itching all over the body (pruritis chronicus senilis), of five years' standing, which had been treated by me about four years without much success, was cured by taking methyl-blue, 0.2 internally, once a day for two months. It was interesting to note that a chronic ulcer of the leg in this patient had meanwhile healed, without any other treatment than it had before.

The above statements show that methyl-blue may perhaps also gain a place in the treatment of diseases of the skin, and is certainly worthy of a trial by dermatologists. I should like to caution my colleagues that in prescribing methyl-blue they make certain that pyoktanin is not dispensed instead, as has been done quite often by druggists; this latter substance being badly borne by the stomach.

I have no doubt—and am here in accord with those gentlemen of this city who have tried and still apply the anilin dyes in the treatment of surgical diseases, and especially in the treatment of inoperable malignant growths (Dr. Willy Meyer and others)—that the anilin dyes will certainly soon play an important part in the various branches of medicine.

Very respectfully,

Max Einhorn, M.D.

120 East Sixty-fourth Street.

Leucorrhœa, is, according to Dr. Louis Bauer, often due solely to constipation, hence clearance of the bowels of their fecal contents is in many cases the chief and most effective treatment of that troublesome disorder.

Dr. Martin Steinthal, of Berlin, the Nestor of the medical profession in that city, celebrated the seventieth anniversary of his admission to practice on November 5th. He was ninety-four years of age on October 22d.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department. United States Army, from November 8, 1891, to November 14, 1891.

HALL, WILLIAM R., Captain and Assistant Surgeon. Relieved from duty at Fort Schuyler, N. Y., and assigned to duty at Angel Island, Cal.

CLENDENIN, PAUL, Assistant Surgeon. To be assistant surgeon, with rank of captain, November 5, 1891, after five years' service, in accordance with the Act of June 23, 1874.

FISHER, HENRY C., First Lieutenant and Assistant Surgeon. Ordered to Fort Riley, Kan., for duty.

SHAW, HENRY A., First Lieutenant and Assistant Surgeon. Ordered to Fort McKinney, Wyo., for duty.

DUNLOP, SAMUEL R., First Lieutenant and Assistant Surgeon. Ordered to Fort Sill, Oklahoma Ter., for duty.

KIEFFER CHARLES F., First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Sheridan, Ill.

MERIWETHER, FRANK T., First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Adams, R. I.

TEN EYCK, BENJAMIN L., Assistant Surgeon. Granted leave of absence for one month, to take effect about the 15th inst.

MEAVUS, EDGAR A., Captain and Assistant Surgeon. Relieved from duty at Fort Snelling, Minn., and assigned to duty at Fort Mackinac, Mich.

WILLCOX. CHARLES, First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Bowie, Ariz. Ter., and assigned to duty at Fort Gaston, Cal.

Official List of Changes in the Medical Corps of the United States Navy for the week ending November 14, 1891.

GATEWOOD, J. D., Passed Assistant Surgeon. Detached from the Despatch, and granted two months' leave of absence.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 14, 1891.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	41	17
Scarlet fever	112	16
Cerebro-spinal meningitis	2	1
Measles	37	1
Diphtheria	107	37
Small-pox	0	0
Varicella	2	0
Pertussis	7	6
Erysipelas	0	0
Mumps	0	0
Rötheln	0	0

Foreign Diplomas are Not Sufficient.—A German physician was arrested the other day in New York for illegally practising medicine without a license. The offender presented diplomas from the universities of Geneva, Zurich, Berlin, and Prague. These were not sufficient, however, to meet the requirements of our law, which says that a practitioner must have a license from the proper authorities in this State.—MR. HENRY A. RILEY, in *Medical Progress.*

Mortality in England and France.—Two hundred years ago the mortality in England was 80 in the 1,000, and fifty years ago 25 per 1,000, while in 1889 it had fallen to 17.85. This result is the more remarkable since the birth-rate is so large, and it is well known that a large birth rate increases the annual death coefficient. In France the mortuary rate, which, at the beginning of the century, was 28, is to-day 22.29, but the coefficient of births has fallen from 30 to 25 per 1,000. If the births in France were in the same proportion as those in England, the increased death-rate over this country would be still greater.—*Journal de Médecine de Paris.*

Tried by a Jury of his Peers.—A practitioner in Innsbruck, in his endeavors to extract a bean from the external auditory canal of a young man, ruptured the drum-membrane, in consequence of which his patient acquired suppurative middle-ear disease and died. The Medical Faculty of Innsbruck thereupon summoned the unfortunate medical man to appear before them, censured him for his want of skill, and deprived him of the right to practise until he should have passed an examination in surgery showing that he was competent.

Treatment of Malarial Hæmaturia.—The following is the treatment for malarial hæmaturia, or swamp-fever advised by Dr. L. H. Davis, in the *Memphis Medical Monthly* for October, 1891: "Give the patient two grain doses of fresh English calomel every three hours until active tarry actions appear, then keep the bowels moving with some saline until the color clears up. The calomel should be given dry on the tongue; don't fear ptyalism; lay aside all prejudice and save your patient. This is not theory. If you think so give it a trial. Give acetanilid in ten-grain doses every three hours till the skin is moist, then quinine in ten-grain doses every four hours for a few doses, lessening the quantity as soon as cinchonism develops. Do not believe that quinine has an injurious effect on the kidneys, as some would tell you, for there is nothing in this whatever. Give bits of ice to allay thirst. Do not give veratrum viride."

The Silly Cyclist.—There are fools among the wheelmen as well as in other bodies of men, as witnesseth the recently concluded six days' bicycle race at the Madison Square Garden in this city. Fortunately for the contestants in that race, or rather trial of endurance, none of them met the fate of the Englishman who died recently after a twenty-five mile race at Doncaster. When nearly at the end of the contest he was observed to be riding in a peculiar way while his wheel was wobbling from one side of the track to the other. He was taken off, but immediately lost consciousness and died the following day. He was said to have been in apparently perfect health when he began the race.

Medical Missions.—China is perhaps the most inviting field for medical missions in all the world, says the Rev. Mr. Blodget, of Pekin. In Japan the native physicians, and in India the army surgeons, are met with as rivals, but in China the medical missionary has it all his own way and can treat without restraint both soul and body of Ah Sin.

Where Travelling is Risky.—A German physician recently left Jena for a vacation tour in Corsica, and promised to entertain his friends with letters from time to time containing realistic descriptions of what he might see and hear in that lovely isle. The first news from him was that he had been arrested as a spy and was getting free board in the jail at Bastia. The exertions of the consul finally secured his release, and he immediately shook the dust of the inhospitable land from his Jaeger shoes, and now the friends in Jena have to study Baedeker for information concerning Corsica. Professor Haeckel had a somewhat similar experience during a scientific tour that he made in Algiers some time ago, being repeatedly arrested as a suspected spy and being put to no end of trouble to prove his innocence.

REPORT OF CASES OF CHOLECYSTOTOMY WITH SPECIAL REFERENCE TO THE TREATMENT OF CALCULI LODGING IN THE COMMON DUCT.

By A. VANDER VEER, M.D.,

PROFESSOR OF DIDACTIC, ABDOMINAL, AND CLINICAL SURGERY, ALBANY MEDICAL COLLEGE, ETC.

MR. PRESIDENT AND FELLOWS: In presenting this paper as a contribution to the surgery of the gall-ducts, I shall refer somewhat to the surgery of the gall-bladder, yet my chief desire is to get from you a discussion and your views regarding a line of treatment in such cases, as where we find a contracted and perhaps almost obliterated gall-bladder, or where the common, cystic, or hepatic ducts are entirely closed by lodgement of a calculus, or stenosis from other causes. I take it that the most of abdominal surgeons are ready, and feel that they are doing full justice, in treating a case like the following according to the methods now employed.

CASE I.—Mrs. S. St. O——, aged forty, married, native of United States, and by occupation a housewife. Family history good; patient had had all diseases of childhood; first menstruated at fourteen, always regular; married twenty-two years, mother of eleven children, youngest aged twenty-two months. First began to feel ill about two years ago. July 12, 1890, patient had a severe pain over region of gall-bladder, and simultaneously a bunch appeared in right side. Pain lasted about four weeks, when she began to improve, but has had repeated attacks at intervals since. Has had sensation of weight in right side since first attack. Appetite poor; continuously jaundiced since about four months ago, which would fade and recur with each attack of colic. In March, 1891, began itching, which was limited to chest. This disappeared for a week, then reappeared on arms, lasting again for a week, and reappeared again in May last, this time general over every part of body, and did not abate.

Physical Examination.—Fluctuating tumor in the region of the gall-bladder, tender on pressure; pregnancy advanced three months; skin intensely yellow. In view of her constant emaciation, the itching yielding to no treatment, notwithstanding her pregnancy, I advised an immediate operation. She was accordingly admitted to the Albany Hospital June 18, 1891, was placed in a private room, and given the usual treatment for abdominal section. Operation, June 20th. Vertical incision over gall-bladder, which was stitched to abdominal parietes and opened. Gall-stones, sixty-four in number, removed, varying in size from a hickory-nut to a small pea, and which I here exhibit. Silver probe was passed through the common duct into the duodenum. Before stitching the gall-bladder in the incision I examined duct carefully and could not detect any calculus there. Drainage-tube (glass) introduced and packed with iodoform gauze. Abdominal wound closed by silkworm sutures. Bowels moved the third day, normal in color, while before they had been of a whitish appearance. Would say here that a few days after the operation, and when the stomach seemed to call for it, she was given the best of nourishment. Her weakness, which was quite marked, demanded it, and her good digestion greatly aided her recovery. Recovery uneventful and uninterrupted. Discharged July 11, 1891, with sinus nearly closed, feeling stronger and looking better than she had for many months. July 25, 1891, she called at my office, saying the sinus had closed a few days after leaving the hospital, that it had remained so for a week, during which time she did not feel so well; that it then began to discharge a whitish secretion, and that she had felt better since. In every other respect she was very much better.

August 14th, she came to my office complaining that the wound had remained closed for a week, and that she did not feel nearly as well in consequence. Dr. Macdonald, my assistant, opened up the wound freely, introduced his fingers into the cavity, and not detecting any foreign substance or hardness, placed in a rubber drainage-tube for more permanent drainage. This relieved her very much, but about September 1st she became suddenly jaundiced, which was quite marked on September 6th, when I saw her, and although not suffering any acute pain, yet she has a loss of appetite and feels some of her old symptoms of itching, general weakness, etc. No marked tenderness in the region of the gall-duct. The cavity of the gall-bladder seemed shrunken and the tube forced out occasionally, but drainage has kept up fairly well. She was given a tonic of bicarbonate of soda, taraxacum, and elixir or cinchona, with directions to return again in a week or two for examination.

Undoubtedly this woman suffered from gall-stone colic, that she got her jaundice from obstruction of the duct in consequence of a stone too large to pass, all of which was relieved by the operation; but that there is left, as a result of previous inflammation, a stenosis of the duct.

The operation in such a case is not a difficult one, and beyond a doubt the results are favorable; but is it not true that this very method of operating has deterred us in some cases from pushing ahead and relieving cases where practically no gall-bladder is to be found? In other words, have we not, from fear of peritonitis resulting and other conditions, been too conservative in attacking our more complicated cases of gall duct obstruction, such as where we have stenosis, severe adhesions, and apparently no gall-bladder present? The intent of this paper is to deal only with those cases where there is an obstruction of the ductus communis choledochus, the cystic, or of the hepatic duct from any cause whatever. The surgery of the biliary bladder and ducts, where the conditions calling for relief lie within the gall-bladder or cystic duct, is, as I have said, reasonably well established. Cholecystotomy, with suture of bladder-walls to parietal wound, when the viscus is fairly well developed, is not a serious operation. Primary and secondary opening of the gall-bladder I mention here to emphasize the fact that I believe the latter is always to be condemned, for the following reasons:

1. It is necessary always, before the closure of the abdominal wound, that the gall-bladder be opened and emptied, as it is often impossible to recognize conditions until then which will require manipulations, not only within the gall-bladder, but also within the abdomen.

2. Prolonged obstruction in the intestinal portion of the common duct may lead to dilatations of it, together with that of the gall-bladder, and the destruction of anatomical outlines. Ideal cholecystotomy, which I have had in mind in leading you on thus far, has doubtless a circumscribed field of application and is confined to cases where the calculi can be completely removed, and the walls of the gall-bladder and common ducts are in a rela-

tively healthy condition; but it is the operation. Biliary calculi lying in the common duct, in the hepatic or at the mouth of the cystic duct; stricture of the ducts from local ulceration (exceedingly rare); or occlusion of them from external causes, as cancer of the pylorus or pancreas, from calculus of the pancreas lying in the last portion of the pancreatic duct, all require treatment for relief beyond either cholecystotomy or cholecystectomy, according to Langenbeck. Let me illustrate a little further.

Case II.—Mr. J. W——, aged fifty-one, English, married, and by occupation a plumber. Habits good; never seriously ill. Two years ago was attacked with severe pain in right side, under free border of ribs, and extending over region of stomach. At times much jaundiced. Pain occasionally very severe; treated by many physicians, and a variety of diagnoses given him. I first saw him in the beginning of December, 1890. He was greatly emaciated, and felt very much exhausted constantly. Little appetite, no thirst; bowels somewhat constipated, and stools for the past year have been constantly light in color. Urine scanty, very dark, and on examination contains bile, but no sugar. Is very much troubled all over his body with an intense itching and slight ecchymotic spots. Cannot sleep and is much depressed, although hopeful that an operation of some kind, or some form of treatment, can be suggested for his relief. On direct examination no tumor can be made out. Liver contracted. Notwithstanding his feeble condition, I advised him to submit to abdominal exploration.

Diagnosis, gall-stone in common duct. He desired a line of treatment first, and that he might consult his family and arrange his business. Accordingly, I placed him upon the best of tonics. January 12, 1891, he was admitted to the Albany Hospital, improved in spirits and ready for the operation. He was greatly jaundiced, and very anæmic. Usual preparatory treatment was given him.

Operation, 11 A.M., January 15th. Usual incision for cholecystotomy. Gall-bladder was found completely contracted, surrounded by adhesions, and held under lower border of the liver. In the common duct, in the finding of which I was somewhat embarrassed, I found lodged a long, large calculus which I here exhibit, and which measures in length nearly two inches, and in circumference almost an inch. I found that it was impossible to dislodge it forward, or pass it into the duodenum and that to crush it by external force would probably destroy the duct. I could not make use of needles to break it up, therefore I was obliged to make an incision through the duct its entire length, over the stone, and in this manner remove it. I had placed previously in the wound a flat sponge, and as the duct was opened there escaped upon the sponge a glairy, bile-stained secretion, a teaspoonful or more. The duct was emptied out, and, as it was believed, a probe passed down into the duodenum. I now made an attempt to suture the incision in the common duct, but in consequence of the depth of the wound, the unyielding condition of the parts, due to adhesions, I found it to be the most difficult operation possible. Sutures were introduced, somewhat after the manner here described. The first row, continuous, were introduced just within the serous coat of the duct and brought just within the mucous coat, but not involving it. The second series, Lembert, bringing the serous coat into accurate apposition.

The operation was a long one, and I was somewhat uncertain as to the thoroughness of the closure. Glass drainage-tube was introduced. Strips of iodoform gauze were passed down to the bottom of the wound around the glass tube and external incision partially closed. Patient rallied very well from shock, etc. In the evening it was evident there was some escape of bile, as shown by the tampon of iodoform, and the latter changed. On the morning of the 16th the iodoform was renewed, and then but once after that, as the gauze continued dry and the parts in excellent, healthy condition. The patient now seemed very hopeful, was hungry and anxious for food. Milk given him quite freely; stomach in excellent condition. Itching gone; no anodynes required. Had slept well during the night; bowels moved slightly by aid of enema, and then after that two or three times daily; passages at first well formed, later almost fluid, very yellow and offensive. Urine improved in color at once, although scanty. He suffered considerably from flatulence, although there was no distention whatever. No pain on pressure over any part of the abdomen. He slept a good deal of the time, and though he took plenty of food by the stomach, yet owing to his great weakness an attempt was made to feed him twice daily per rectum. This, however, was not very successful. The flatulence was relieved by small doses of carbolic acid. No vomiting at any time. All seemed to be progressing well. Saw him at 9 P.M. the 19th; his pulse was very good, and I felt much encouraged. After midnight he presented symptoms of heart failure; stimulants, digitalis, etc., used, but he died somewhat suddenly at 6 A.M., January 20th. No autopsy granted, much to my regret.

Case III.—Mrs. H. H——, aged forty-eight, married, English, housewife by occupation, and mother of several children. For the past two years has suffered a good deal from repeated attacks of biliary colic, and been told her true condition by several physicians who have treated her during the past eighteen months. She has evidently undergone a clear line of medical treatment, but without much benefit. Two years ago she was treated for an acute attack of albuminuria, from which she made a good recovery, but since then has developed her jaundice, itching, emaciation, pain, and all the symptoms of obstruction of the gall-ducts. Is a lovely woman in disposition, and anxious for an operation or any line of treatment that will afford relief. Says she cannot live on in her present sufferings. Her case in many of the symptoms is precisely like Case II. She was admitted to the Albany Hospital April 20, 1891, for treatment and operation. I desire to say here that all three of these cases had, at my suggestion, first tried large doses of olive-oil, but without benefit. After proper preparatory treatment, moving of bowels, etc., and following use of oil with iron and quinine, as well as giving bicarbonate or phosphate of soda and the acid treatments a trial, but without effect except to improve her strength somewhat, the operation was done May 22d. In reviewing the history with the patient a little while before the operation, I learned that about a year previous she had suffered from a well-marked attack of localized peritonitis on the right side.

The usual vertical incision was made, and longer than I have generally employed. The gall-bladder, after much searching and the breaking up of many firm adhesions, was found underneath the border of the liver, and entirely collapsed. I could not make a successful exposure of the ductus communis owing to the many adhesions. I made a crucial incision of the external wound used retractors, and by the aid of flat sponges pressed back the viscera, giving a little better view of the surgical landmarks; but the best efforts gave me only the result of feeling what I believed to be a good-sized gall-stone lodged in the intestinal end of the common duct. I made firm pressure on it with my thumb and finger, and though somewhat uncertain, yet thought I moved it into the duodenum, and that it was partially crushed under my manipulations. Other organs in the neighborhood seemed normal, so far as adhesions would allow of an examination. Wound was closed by interrupted silk-worm gut, no drainage. After the operation, and for three days, the patient vomited quite freely, at times a decidly greenish, bilious-looking substance. How much this had to do with the further dislodgement of the stone I am not prepared to state. Patient otherwise made an uninterrupted recovery, and left the hospital June 7th. Itching was relieved within a few days; stools became normal, something she had not noticed in over a year; urine light in color, and appetite more than good. She had gained also in weight.

This case has given me much thought. From the improvement that followed we must have dislodged the stone, but had I not accomplished this, what could have been done? I do not think the case could have been treated by incision—that is, in the space allowed suturing could not have been carried out. Then, again, incising the uncovered duct would have been somewhat dangerous, owing to the close proximity of large vessels that could be observed.

A fistulous tract might have been established. Suturing the nearest portion of the small intestine to the cystic end of the common duct might have been a success, and which I would favor in another similar case. The last two cases illustrate what I wish to bring out in this paper, viz., the difficulties of treatment where we have a collapsed gall bladder and strong, firm adhesions. Like all abdominal work, experience is of value. It is very necessary the bowels be put in as placid a condition as possible, that we do not hesitate to make a free external incision, crucial if required, to aid in separating adhesions. Work cautiously but fearlessly. In view of the many cases of gall-stone obstruction that are known to die either from acute or chronic conditions, without operation, we should at present bring our skill to bear in making the operation, when it is performed, as successful as possible in one way or another. Let me state here that I believe it is possible to loosen freely adhesions that have formed in the region of the gall bladder, and that in all cases of severe traumatisms, of whatever nature, we should not hesitate to make free use of the tamponade of iodoform gauze as drainage, or employ the method that has been so clearly recommended by one of our fellows, Dr. Morris.

In relation to suturing of the incision made into the gall-duct, one of the best papers on the subject is that of Dr. H. O. Marcy, in his pamphlet entitled "Relief for Biliary Obstruction," where the steps of the operation are very clearly defined.

I offer the following notes and abstracts as bearing upon this paper, and for the relief of these conditions:

1. Dislocation of the calculus *en masse*, either into the duodenum or into the gall bladder.

2. Cholelithotrity, either by crushing through the walls of the duct with padded forceps or fingers, or from within the gall-bladder by means of the needle or fine probe, followed by removal by the way of the gall-bladder or intestinal canal.

3. Breaking of the calculus by the introduction of strong needles through the walls of the ducts and subsequent dislodging of them.

4. Cholecystenterostomy, according to v. Winiwarter, or modifications of it, as has been suggested by Gaston, of Atlanta, in his elaborate experiments upon dogs.

5. Incision of the gall-ducts and removal of the calculi, with subsequent suture of the incision in the duct, or incision of the duodenum and reaching the duct from that end, as has been done by Dr. McBurney.

The application of all of these methods, for the treatment of the conditions which we have under consideration, involves the controversion of some notions in surgery which, to my mind, are altogether fallacious. The first, that sutures can never be applied to the gall bladder and ducts with safety. The first cholecystotomy was followed by suture and recovery, as well as many subsequent ones, notably a series of thirteen by Heusner, elsewhere referred to in this paper. The second notion is that the healthy biliary secretion always, when free in the abdominal cavity, causes peritonitis. This is equally fallacious. The experience of Schuppel, Boström, the cases of Parraisse, Sabatier, Thiersch, Heusner, Landerer, and myself, are a few of the many demonstrations to the contrary of this dogma. The peritonitis and fatal results of wounds and rupture of the gall-bladder are not caused by the extravasation of pure bile, but from accompanying injuries, as rupture of the liver, or intestinal canal, and hemorrhage, or from an empyæmia of the gall-bladder, and the presence of attendant micro-organisms.

In order to proceed to a more satisfactory position in the surgery of the gall-ducts we must put these notions behind us, as we have many of the ideas concerning the technique and management of abdominal section. These notions must be placed in experience alongside with flushing the abdominal cavity with solutions of bichloride of mercury and carbolic acid, treating peritonitis by opium narcosis, and the extra-peritoneal treatment of the pedicle in ovariotomy, as well as that other obscure and unthinkable dogma, "When in doubt, drain."

I believe in a wholesome fear of the peritoneum, and in the throwing about our patients every safeguard possible. I should not like to complete an operation, knowing that bile might flow over the intestines in the vicinity of the wound, but I believe that such wounds, by proper drainage with glass tubes and iodoform gauze tamponade, can be made comparatively safe for the patient—at least much safer than the condition for which the operation was undertaken.

Those cases which present the least difficulties are the ones in which the calculi can be removed *en masse*, by pushing them either into the gall-bladder after cholecystotomy (preferable), or into the duodenum. Calculi should not be of large size if introduced into the duodenum, on account of their producing intestinal obstruction later. Fracture or incision, and removal from the intestine, can be employed. Sprengel [1] shoved a large calculus into a diverticulum of the dilated duct, supposing it to be the duodenum, without relieving his patient. The danger of tearing the duct across its diameter, as has already occurred, must be kept in mind and will necessarily circumscribe its employment. The second procedure, together with the third, may be employed in suitable cases, but the question will always arise between them and the employment of the fifth procedure, that is, incision and removal.

The fourth method of treatment, by establishing a new communication between the biliary ducts and the intestine, must have always a certain utility, especially where it is found that the seat of obstruction (the common duct) is bound down by adhesions, and cannot be made accessible or perhaps not found at all—the experience of many operators. Then, if a communication is sure between gall-bladder and the liver, a cholecystenterostomy can be performed. Here a modification of Senn's decalcified bone plates, or the segmented rubber rings, can be employed and an anastomosis made. By this method I believe the operation will be greatly hastened.

To one doing abdominal work, and especially about to operate upon the gall-bladder or ducts, I would advise a careful perusal of the experiments made by Dr. J. McF. Gaston, of Atlanta, Ga., in a paper entitled, "Experimental Cholecystotomy." [2]

In France, the operation bearing the name of v. Winiwarter has recently received much attention, and very flattering results have been reported. In pursuing the study of this operation it was of great interest to find the report of an autopsy by Kappeler (Virchow-Hirsch, "Jahres-berichte") of a patient dying from other causes who had fifteen months previously been operated upon according to the operation of v Winiwarter. The fistula established was about eight feet from the ileo-cæcal valve, and over its intestinal orifice had a valve which only permitted the contents of the gall bladder to pass readily into the intestine, but prohibited the passage of intestinal contents into the gall bladder. This case is exceedingly interesting, showing that it is not so absolutely necessary to use the duodenum, or get so very near the opening of the common duct.

Under the fifth division, that is, incision and suture of the gall ducts, we have, I believe, in many cases a method which promises great success, where heretofore the cases

[1] Verhandlung der Deutschen Gesellschaft für Chirurgie, 1891.
[2] Atlanta Medical and Surgical Journal, 1884.

have been treated by the establishment of biliary fistula, which only relieved for a short time. All these patients eventually died, that is, with biliary fistula, apparently not getting entirely well.

It is true that my patient (Case No. II.) died, but there was no peritonitis, and before operation his condition was very serious, being already cholæmic, with those changes in pulse and heart which accompany this condition. His death may be attributed solely, in my mind, to exhaustion consequent upon his condition prior to the operation. So far as I am able to learn, incision of the common duct has been performed seldom in this country. Marcy refers to it in his last pamphlet. Küster, Kümmel, Braun Rehn, Heusner, have reported each a case, and Courvoisier three cases.

The technique of the operation, for incision of the common duct, I would refer to as follows:

The usual vertical incision from the tip of the cartilage of the tenth rib is made of sufficient length to permit of free examination. In some cases, for the completion of the operation it may be necessary to make a transverse incision through the right rectus abdominalis. An incision over the stone in the line of the duct is made. If any considerable fluid is behind it, in the duct, it had better first be withdrawn by an aspirator, otherwise sponges may be placed so as to protect the surrounding parts, the incision made, and the removal of the stone accomplished. The introduction of the sutures requires great care, a spear-pointed, curved needle, point full, with a round shaft—such as the very finest used for work on the cervix, is most suitable—a good needle-holder, of small pattern, and aseptic sutures of any kind, preferring the iron-dyed silk No. 6, are all that is required. The first row of sutures, continuous, introduced just within the serous coat of the duct and brought just within the mucous coat, but not involving it; the second series, Lembert, bringing the serous coat into accurate apposition.

The suturing completed, to avoid the extravasation of the fluids, if the stitches should give way, a glass drainage-tube should be introduced (Price's pattern) so that the bottom end rests lightly over the line of the sutures. The tube is then to be surrounded on all sides by an iodoform gauze tampon, the ends of which are left in the abdominal wound. Closing the latter with silkworm gut sutures ends the operation. One or two silkworm gut sutures may be introduced and tied in a loop, so that after the removal of the tamponade, after forty-eight hours in favorable cases, they may be tied and the abdominal wound more completely closed.

The Same Old Story.—Medical men practising in the poorer districts of London have, like their brethren elsewhere, long been complaining that their ordinary patients are taken from them by the free hospitals and dispensaries. Hitherto, however, their midwifery patients have been spared to them. Now, according to the *Hospital Gazette*, even these are to be taken away from the unfortunates practising in the King's Cross district. In order to give the women students "walking" the Royal Free Hospital instruction in practical midwifery, the authorities have, we hear, opened a midwifery department, through which women residing within about a mile of the hospital in Gray's Inn Road can be attended, during the lying-in period, by lady students, free of charge. As many of the doctors in that district derive a great part of their income from half-guinea midwifery fees, the competition of the hospital will, to them, be a very serious business.

Will do Better Next Time.—An unique attempt at suicide was made recently in this city by a man who jammed a teaspoon down his throat. In what way he expected it to act we have not learned; but the would-be suicide is evidently a man of determination and is not one to be balked by one or two failures.

A PLEA FOR FULL MECHANICAL DILATATION OF THE PARTURIENT CANAL BEFORE OBSTETRICAL OR GYNECOLOGICAL OPERATIONS.[1]

By GEORGE E. ABBOTT, M.D.,

NEW YORK.

Mr. President and Fellows: Some time since, I was engaged to attend Mrs. G——, a multipara, for her confinement. Upon reaching her bedside she said she would not have called me so soon, but that she feared the bladder was coming down in front of the child. Inspection showed an immense hypertrophy of the membranes, tough and strong, and an excessive amount of liquor amnii, so that the entire parturient canal, including the vulva, was dilated to its utmost, and a bag of waters as large as a full-sized head had already been born. Upon examination there was found a vertex presentation, but that the head had not engaged, and was still at the superior strait. On rupturing the membranes the waters poured out, and within six minutes thereafter a large child was born.

There seemed to me in this case a principle involved which might be of useful application, and upon meditation there came clearly to mind, one after another, the advantages of a full mechanical dilatation of the cervix, vagina, and vulva before the application of the forceps, or other obstetrical operations, and I would ask you to follow me for a few moments in considering them.

Let us recall some of the injuries of parturition, whether caused by nature or by the accoucheur, either from too great haste, carelessness, or excitement, or by urgent necessity, and then see whether the proposed method will not probably remove the cause, prevent the injuries, and alleviate or abolish the sequelæ.

In cases of puerperal eclampsia this method is not applicable because the labor must be terminated as soon as possible. The canal must be forced open and the child extracted immediately. There is no time for medication, nor Barnes or Molesworth dilators, nor yet for any careful and full dilatation.

In those cases of interference, however (which are by far the greater number), where nature must be helped surgically, but where there is no vital need for haste, this method is applicable, and should, I think, be practised; in fact, in all cases where there is time, to properly dilate the undilated passage (the mother and child both being safe), and then having done so, complete the delivery as soon as possible. And this method would seem to be specially efficacious and desirable where we have to apply the forceps, because then we must proceed slowly for the mother's, but rapidly for the child's sake, so as to prevent laceration of the maternal parts, and compression of the child's head, with its sequelæ, which are too often overlooked and placed in the category of diseases of the "newly born" without seeking their full etiology. By first fully dilating the parturient canal, as above suggested, we accomplish both of these objects, and secure a rapid and safe second stage.

One author says, "A rigid os—vaginal bands—persistent hymen, and a pathological perineum demand the forceps." To my mind they demand a careful mechanical dilatation, aided, if necessary, by the knife or scissors, until the passage is cleared of obstructions and sufficiently enlarged. This should be done prior to the application of the forceps, and I am confident that if this course be pursued many of the injuries liable to accompany the use of forceps without first dilating will be avoided. Consider how changed the conditions would be. After carefully and scientifically removing all obstructions and dilating the canal, with what comparative ease the forceps could be applied, and how promptly and safely the child could be delivered, with a minimum of laceration for the mother and danger to the child. It is the gain to the delicate structure of the cerebral substance and the sensitive membranes of the child that we

[1] Read before the New York Harvard Medical Society.

should consider, as well as the prevention of maternal lacerations.

In version we find that a living child may be rapidly brought through a well-dilated passage, while the delay in slowly dilating the track with the child's body, with its attending long compression of the cord and an impacted after-coming head, gives us a still-born child. With a large exit there is not so great a tendency for the arms to be carried over the head.

In dystocia from inertia the suggested dilatation of the vulva is often sufficient to bring on good bearing-down pains, for the dilating hand gives the same reflex irritation that the head does upon the perineum, which encourages the uterus and calls into action all the force of the abdominal muscles to complete the expulsion of the child.

Herein, however, lies one serious objection to this plan, viz., that in case of tetanic or excessive uterine action, with an unremoved obstruction, the perineal reflex should not be excited. In these cases the dilatation should be postponed until the excessive action is overcome by anæsthetics or anodynes.

As to embryology, craniotomy, decapitation, vaginal hysterectomy, delivery of fibroids, and so forth, mere inspection of the accompanying cuts (Figs. 1 and 2), which should be compared perpendicularly, must make it apparent to all that the canal should be fully dilated before operating, so as to secure ample room for so doing, and especially for the removal of the sharp bony fragments; and yet the present practice is for the accoucheur to commence proceedings by introducing his instruments as in Fig. 1, the passages being all of them relatively contracted, and not until he has consumed much time, and possibly done much damage, accomplishing little, if any, good, has he, by his awkward movements, unintentionally dilated the parts, as in Fig. 2, and not until then can he do effective work. How much more scientific to do this dilatation, in the first instance, properly and with a purpose, and thus avoid the unfortunate accidents often occurring.

In regard to mechanical dilators, there are perhaps none better than the old ones, Barnes's and Molesworth's, and the vaginal and cervical tamponades; but, best of all, the hand. And in the use of any dilator, the hand or any other, care should be observed in the matter of antisepsis. At a discussion on this subject in one of the leading medical societies of this city much was said as to the surgeon's hand, his toilet, his finger-nails, etc.; but nothing in regard to the corkless vaseline bottle, that culture-den of microbes, nor of the patient's vulva, with all its capillary forest, infested with bacteria from which the most thoroughly aseptic hand must carry whole armies of bush-whackers into the very citadel we wish to guard most carefully. Also let us not forget to cover unwashed blankets and comfortables with a clean sheet, to thoroughly sterilize the patient's vulva, abdomen, and thighs, and where the bichloride solution is used, to be sure to replace the natural mucus by some aseptic lubricant.

In regard to the dilating hand, let me suggest the desirability of the accoucheur reducing the size of his hand

Fig. 1.

Fig. 2.

Fig. 3.

Fig. 4.

by frequently pressing and squeezing it with the other hand, or better, by using a lubricated funnel of wood or metal, as in Fig. 3, by which the circumference of the hand is materially reduced, and its flexibility increased without impairing its strength.

In operating, pass the hand through the vulva in as small a cone as possible (Fig. 3), then dilate the cervix carefully with the fingers, avoiding rupture of the membranes. While the fingers are at work within the cervix, let the hand and forearm be at work on the vagina and vulva. The perineum can be finally dilated by the forearm. The dilating hand should not be repeatedly inserted and withdrawn from the vulva, thus carrying sepsis with it, but should remain in the vagina until dilatation is quite complete, frequently closing the hand carefully into a fist, as in Fig. 4, partially at first and then larger; this will increase its dimensions, giving the dilatation required.

The hand should be rotated but sparingly, and with much caution. It is much better to avoid rotation and to carry the hand bodily from pubes to coccyx, and from one ischia to the other. During all this, let an aseptic towel be wound around the arm, which shall form a washer or cover to the vagina.

This at first may seem like "meddlesome midwifery,"

but on careful consideration I believe it will be found scientific surgery.

I do not advise this mechanical dilatation in all cases, but only where it is indicated, and I believe it to be indicated in most cases where anæsthetics are given; and although it requires a few minutes' time, it will usually be when both mother and child are safe, and the time can be taken, and I am confident that the result of the operation will be far better and much safer to both, and will in this way save much time otherwise occupied in a tedious convalescence from possible injuries. I shall surely be asked what is the percentage of my results? This I am unable to answer, for I have not as yet practised the method sufficiently long to have established a percentage, but in *every* case thus far I have secured the most satisfactory results.

I have brought this subject before you in the hope that others will examine into it, and practise it, and thus through the extent of its use we may soon arrive at reliable conclusions, which are impossible without considerable lapse of time in the practice of one only.

The gist of all this is, first, to secure ample room in which to operate; second, having begun the second stage, to complete it more rapidly; and third, in operating, to do less injury to both mother and child.

Some of the advantages of fully dilating the parturient canal before operating are: A decidedly better diagnosis of position and of any complicating obstructions; easier application of the forceps; less likelihood of lacerations; next to the normal bag of waters, the most scientific and careful dilatation of the canal; less danger of still-birth or long compression of the head, with its sequelæ of diseases of the newly born; less need of forcible pressure from above; less danger of extension of arms; stimulating the atonic womb and abdominal muscles, in cases of inertia, and at the same time preserving the womb's strength for post-partum contractions; the avoidance of continued pressure upon the pelvic nerves, with its sequelæ of paralyses, inertia, post-partum hemorrhage, and phlebitis; greater freedom of operating; more room in which to remove the bony fragments. Moreover, the child remains unmolested and in safety until such time as the maternal parts are adapted to a safe and speedy delivery.

A NEW METHOD FOR THE ADMINISTRATION OF THE IODIDE OF POTASSIUM.

By D. BRYSON DELAVAN, M.D.,

NEW YORK.

THE irritating effects of iodide of potassium upon the stomach, and the difficulty of administering it in large doses in many cases in which it is necessary to bring the system rapidly under its influence, are well known, and have been the occasion of numerous efforts to correct these disadvantages.

The ends to be gained in giving the iodide are, (*a*) thoroughness and rapidity of assimilation, (*b*) administering it in such a manner as to render it unirritating, and (*c*) sustaining the patient's nutrition during the period of its administration.

To meet these requirements it has been suggested that the dose for twenty-four hours be subdivided into a number of small portions, to be given six, eight, or even twelve times per diem, instead of in the usual triple dose. In order to aid its assimilation it has been given in solution with wine of pepsin as a menstruum, and, for the above purpose also, and to render it unirritating, as well as to secure to the patient a certain amount of nutriment, the excellent device has been practised of giving it in milk. It has also been given hypodermically, and by the rectum, and is often prescribed to be taken in Vichy water. Of the above methods, those in which wine of pepsin and milk are employed are the best; indeed, the latter marked a distinct advance in the use of the drug, and has proved to be exceedingly valuable, disguising to some extent the taste of the iodide, causing it to be less irritating, and affording with each dose a small but desirable amount of food. The substitution of the article known as "matzoon" in the place of milk is often advantageous, and an improvement upon the latter.

The writer has had opportunities of studying many cases of active tertiary disease of the thorax, and has experimented with various methods for the purpose of overcoming in such subjects the following common difficulties, namely, pain and difficulty in swallowing, gastric irritation, faulty assimilation of the iodide, loss of appetite, and distaste for food, and finally, general depression from lack of nourishment; and has found that all of the desired indications may be most satisfactorily met by an exceedingly simple device.

If pepsin be added to warmed milk the result is the well-known article, "junket," "rennet custard," or "rennet curd," the pepsin acting upon the milk as a digestive, and causing it to curdle and to form a delicate, jelly-like mass, which is attractive to the eye, palatable to the taste, more easily swallowed than anything, perhaps, but an oyster, and remarkably easy of digestion and assimilation. This curd forms an admirable vehicle for the administration of the iodide, and in the proportion of ten grains of the iodide to four ounces of milk effectually disguises the taste of the salt. If a stimulant be required, a little sherry wine may be added. The iodide should be used in a saturated solution with water, one drop of which equals one grain of the drug. Any good pepsin may be employed; that which the writer has found most effective in its prompt and thorough action upon the milk, and most agreeable to the taste, is the so-called "Fairchild's essence of pepsin."

To administer a five-grain dose of the iodide, place five drops of the saturated solution of the iodide in the bottom of a small tumbler, with fifteen drops of essence of pepsin, and if desired, a teaspoonful of sherry, upon this pour two ounces of warm milk, and set away in a cool place. The milk must not be too hot, as otherwise the digestive properties of the pepsin will be destroyed. Coagulation soon takes place, and the mixture is then ready for use.

For the general convenience of the patient the following formula may be dispensed:

℞. Potass. iodid. (sat. sol.)..... 160 grs.
Essence of pepsin..... ℥ j.
Sherry wine.....q.s. ad ℥ iv.

M. Sig.: ℥ j. in four tablespoonfuls of milk, according to directions.

While this method may not be necessary in many simple cases, there are, nevertheless, a very considerable number in which it may be employed, and in which it will be found to fill the required conditions better than any other now in use.

The New Russian Pharmacopœia, now in press, will contain 808 articles instead of 1,026 in the last edition. One hundred new articles have been added, while 318 old ones have been omitted.

Inebriety and Medical Practice.—A Cincinnati evening paper, commenting upon the Georgia law concerning physicians addicted to alcohol, says that legislation of a similar kind is needed in Ohio, as a few days since a Cincinnati physician was taken off the streets suffering from delirium tremens, while still another was locked up in the workhouse convicted of habitual drunkenness. And one of the most prominent men in the Cincinnati Medical Society, some years ago, conscious of his consuming appetite for rum, invariably wrote his prescriptions twice, each time keeping a copy, thinking thus to escape any mistake which he was fearful he might commit while intoxicated.

REMARKS ON FRACTURE OF THE STERNAL END OF THE CLAVICLE DUE TO MUSCULAR ACTION.[1]

Report of a Case Caused by Coughing.

By ADOLPH RUPP, M.D.,

NEW YORK.

"The clavicle is more frequently broken than any other bone in the body except the radius,"[2] and more than one-half of the fractures of the clavicle occur before the end of the fifth year of life, and during this period of life they occur with about equal frequency in both sexes. After the fifth year these fractures happen oftener to males. In seven hundred and seventy-two fractured clavicles treated at the Middlesex Hospital during sixteen years (452 males, 320 females) only twenty-eight times was the fractured clavicle found in people (18 males, 10 females) over sixty years of age.[3]

The late Doctor Lente found the sternal end of the clavicle fractured only three times in one hundred and fifty-eight cases of fractured clavicle.[4] And Stimson says the fracture may occur at any point of the inner third of the clavicle.[5]

It will have been inferred from the foregoing facts and statistics that fractures of the inner third of the clavicle are relatively very rare occurrences; and this is so for any and all causes.

Fracture of the clavicle due to muscular action is rare. In 1864 Gurlt collected twenty cases of fracture of the clavicle due to muscular action, and found most of them fractures of the middle third. In 1873 Delens collected eight cases of fracture of the inner third of the clavicle—the fractures due to muscular action.[6] And cases of this kind, says Gurlt, are not necessarily accompanied by any bone disease as a causative agent.

Accidents of this kind are due, according to Erichsen, to back-handed blows, or, as Gurlt puts it, to some forcible backward movement of the arm.

Before detailing my own case I shall cite three cases which illustrate the manner in which these fractures are produced.

Willard Parker, M.D., reports the case of a mulatto, who was a sportsman, and in a bad state of health, and who, while attempting to strike a severe blow at a dog, broke his right clavicle at the junction of the middle and inner thirds. Union favorable.[7]

W. E. Whitehead M.D. (Surgeon United States Army)[8] reports[9] a case from David's Island, N. Y., as follows: A German, twenty-eight years of age, while trying to raise himself to the top of a platform, felt a snap near his left shoulder, to which he gave no further heed at the time. He slept well during the ensuing night, but next morning experienced pain when he attempted to recline on the left shoulder. A transverse fracture was found at the edge of the trapezius muscle, at about the junction of the outer and middle thirds. No discoloration, nor swelling of the tissues was found at the seat of fracture. This man had relatively large muscles and small bones.

Stimson quotes the case of a boy (from Le Gros Clark) who, while swinging by the feet from a trapeze, tried to raise himself so as to seize the bar with his hands; the clavicle broke in its inner third.

And now my own case. Mrs. L. G——, sixty-nine years of age, the subject of typical scoliosis, bronchitis, and emphysema, while lying abed on her left side, and while coughing, stretched her arm around and backward to grasp a mug from a chair that stood at the head of the bed to her right. While doing all this, in much less time than it takes to tell it, she felt a snap and stitch of pain at the upper portion of her chest, to the right of the sternum, which startled her. On looking she found a protuberance at the seat of pain. When she kept quiet there was no pain; but it hurt her whenever she coughed or moved her right arm and shoulder. Several days after the occurrence of the accident I was called to see her, and found a transverse fracture one and one quarter inch from the sternal tip of the clavicle, and four inches from the acromial end to the fractured end of the sternal fragment. The outer end of the sternal fragment was directed slightly upward and inward, and overlapped the acromial fragment about one quarter of an inch. The fracture was just to the outer edge of the sterno-cleido-mastoid muscle attachment, and this muscle was more apparent than the same muscle of the left side. There was no extravasation of blood, and neither was there any amount of tissue-swelling worth noticing. There was crepitus—not the crepitus of roughened bone edges, but the crepitus of bone rubbing over bone—and pain when the fragments were manipulated.

The woman is much emaciated, and her muscles, otherwise than large and powerful, can be felt under the loose skin; and the bones—clavicles and ribs—can be seen and felt along their entire length. Cases like Parker's, Whitehead's, and mine are easy to diagnosticate; but writers as experienced as R. W. Smith, M.D., have had reason to write as follows: "The subject of fractures engaging the extremities of the clavicle is one of importance to the practical surgeon, inasmuch as these fractures are frequently the source of embarrassment in diagnosis. The absence of appreciable displacement in some of them, and the resemblance which others bear to dislocation, are the chief causes of uncertainty."[1] And by way of contrasting the cases I have cited with what a recent much-praised writer feels himself justified in teaching on this subject, I shall quote from Hoffa's, in many respects admirable book[2] on "Fractures and Dislocations." Hoffa says: "Usually no displacement occurs at the sternal third (in cases of fracture of the clavicle), for that is possible only when the periosteum, muscles, and sternoclavicular ligament are torn, and a non-serrated fracture obtains. . . ." And he goes on to say, "When displacement of the fragments does occur, the sternal fragment remains *in situ*, the acromial fragment pointing upward. If the fracture is due to muscular action, extravasation of blood and swelling are found along the bone, and if crepitus cannot be felt, localized pain will be the pathognomonic sign." All this that Hoffa says is not impossible and may fit the accident at times, but mine and the other cases cited demonstrate that his quoted assertions are somewhat misleading. The probable efficient agents at work in producing Mrs. L. G——'s fracture were the clavicular fibres of the deltoid and pectoralis major muscles, which, contracting, drew the inner portion of the clavicle downward and outward, and the clavicular portion of the sterno-cleido-mastoid muscle pulling in antagonism upward, the first rib acting as a fulcrum against which the contending forces were exerted. The peculiar voluntary movements of the woman, already described, coughing at the time, favored and accentuated the action of the forces just mentioned.

INTESTINAL ANASTOMOSIS.

By BENJAMIN T. SHIMWELL, M.D.,

DEMONSTRATOR OF SURGERY IN THE MEDICO-CHIRURGICAL COLLEGE, PHILADELPHIA, PENN.

SINCE the introduction of Senn's method of intestinal surgery various operators have endeavored to modify the technique and apparatus. While some advantage has been gained, there has been much that has not proved of any material value.

I have written this paper to call attention to a few points that seem to be overlooked in the technique of this special branch. These are factors when rapidity is a necessity.

In my paper read before the Philadelphia County Medical Society, April 12, 1890, I discussed the value of the various rings in use at that time. This was based on a great number of operations. Since then I have found no reason sufficient to alter my first conclusions.

Brokaw's ring, for simplicity of manufacture, ease of introduction, and completeness of coaptation, has not been superseded. Senn's plate stands prominent in gastro-duodenostomy for maintaining firm coaptation and preventing stenosis by contraction. The stomach-ring can be less decalcified than the duodenal plate, therefore resisting the action of the secretions for a longer period.

Dawbarn's vegetable plates are a new feature. They have the advantage of being easily obtained and are easy of dissolution, but are impracticable, except when used in the method he suggests.

The time required for an intestinal anastomosis by lateral approximation is but ten minutes from beginning to end. The new methods have not decreased, but rather lengthened, the operation. This increase has been made by the efforts to render the opposing bowels more secure Various sutures have been advised for this purpose. Operations frequently repeated have convinced me that if the approximation ligatures have been introduced at a proper distance from the incision in the bowel and properly tied, firm coaptation will be got sufficient to prevent fecal extravasation. It is in the tying of these ligatures where success lies.

If your assistant knows the technique he will give invaluable aid at this stage of the procedure. He will so bring the opposing bowel into relation that the lateral walls of the intestines will well overlap the point of ligature; then if the ligatures have been introduced at the proper place the knots will be thoroughly hid. It is a fact that much fault lies in two defects in tying these ligatures either too tight or too loose, therefore necrosis by pressure or lack of firm coaptation. .

To show the superfluity of complicated stitches I wish to make the statement, which experiments prove, that in an injury to the intestine, either by accident or design, paralysis occurs, consequently absence of peristalsis, therefore absence of gas and fecal matter in the portion of bowel operated on; distension does not occur, consequently no tension. As neither gas nor fecal matter can enter a paralyzed gut, we can readily see the uselessness of sutures to support. Obstruction from paralysis shows the paralyzed portion of gut empty and distention in the proximal portion.

Recognizing this fact, I have contented myself, when I thought additional security was necessary, by the introduction of two or four interrupted sutures around the area of approximation. These have given me all the results desirable.

I have advised an additional continuous suture in ileocolectomy by approximation, to give support, as I consider the approximation at this place unreliable, made so by the anosmic action of the colon.

I have had the most excellent results in gastro-duodenostomy by simple approximation, though I consider Weir's method as very advisable to prevent dragging.

Scraping of the peritoneum was advised by Dr. Davis, of Alabama. It has no advantage over scarification, and the possible disadvantage of exposing muscular tissue to muscular tissue. The intestinal tissues in obstruction are rendered exceedingly soft by extravasation and inflammation, and are easily removed. I have seen the most perfect union where neither scarification nor scraping had been done.

The scraping of the invaginated portion is unnecessary; it consumes time. I have seen the whole of the invaginated end entirely covered with plasma in dogs that had been killed four hours after operation. The sutures would be completely hid.

In sewing the invagination three whip-overs of a continuous suture will be sufficient. The mesenteric side is secured first by a snug knot, the forceps holding the inverted portion until the second whip over is entered; then they are withdrawn.

The method of attaching the bowel before incision is unique. The advantages claimed are: better coaptation and prevention of fecal extravasation over coaptating surfaces. These are accomplished at an expense of time and labor.

The free use of distilled or boiled water will obviate any fear of septic infection. The introduction of the sutures and plate has not the same facility as the original method.

Coaptation is perfect if made so. Time is the object, security to the patient being understood.

1253 SOUTH SEVENTEENTH STREET.

CASES OF COCKLE-BURS IN THE LARYNX.[1]

By FRANCIS L. PARKER, M.D.,

PROFESSOR OF ANATOMY AND CLINICAL LECTURER ON DISEASES OF THE EYE AND EAR IN MEDICAL COLLEGE OF THE STATE OF SOUTH CAROLINA, CHARLESTON, S. C.

COCKLE-BURS in the larynx are rare. They are still more rare in the trachea. The reason is obvious. The superior and inferior vocal cords afford a sensitive guard to the windpipe. Occasionally, in sudden respiratory movements, these guards or gates are opened or taken by surprise and the foreign body escapes into the windpipe, then contracting afterward it effectually closes the gate of exit—"the portcullis falls."

Between December 19, 1889, and January, 1891, it has been my fortune to have four cases of burs in the larynx. That is, they were in the laryngeal pouch, in "sacculus laryngis," all visible and located by laryngoscopic examination. The first and third were cockle-burs, the second and fourth were somewhat smaller bodies, called cockspurs.

These bodies, with their numerous small projections, present unusual difficulty in their removal. The subjects are as a rule young and unmanageable, the body small and covered with sharp points, so that the slightest manipulation causes such pain and spasmodic contractions of the glottis, that it is almost impossible to make the necessary examination and remove them, even with cocaine.

The first case presented urgent symptoms, requiring operation on the third day. This was successful. The other three were treated on the expectant and palliative plan, and nature relieved the difficulty. In each case the position of the body was defined, and they were all in the laryngeal pouch. The voice in all four cases was lost for the time. It was subsequently restored in a variable time after the foreign body was expelled.

The object of this paper is to show that when burs are confined to the larynx, in the pouch above the cords, when they are visible with the laryngoscope and yet cannot be removed, and the case can be daily seen and watched (unless symptoms become urgent), expectant treatment is comparatively safe for the patient. The bur will be expelled and the voice restored in a given time.

On the other hand, when the foreign body is in the trachea, invisible with the laryngoscope, operation at the

[1] Read at the Annual Meeting of the South Carolina Medical Association, June, 1891.

earliest moment is usually imperative (though exceptions in the case of burs and other foreign bodies do occur); and as a rule, if not done promptly, death is almost always the result sooner or later.

When the foreign body is in the laryngeal pouch it becomes fixed, when in the treachea it is movable, often changing its position throughout the length of the tube, giving rise to repeated paroxysms of pain and suffocation. This is not the case when the body lies immovable in the laryngeal pouch. The symptoms of almost any foreign body in the air passages are appalling at first; suffocation seems imminent, the distortions, terror, and anguish of the patient need not be described. Hope deserts the little sufferer, and the mother breathes a prayer that death may end the sufferings of her child.

With a change in the position of the body, caused by the apparent death-struggle, temporary relief is afforded. "Hope springs eternal in the human breast," and now, in these periods of relief, patient and parents alike cling to it like an *ignis fatuus* leading the follower on to destruction. The surgeon arrives—the patient is for the time comparatively easy. though there is stridulous breathing and the voice is only a whisper. There is something peculiarly touching as the unfortunate points with the forefinger to his throat, with eyes begging piteously for relief.

An examination is made with the laryngoscope. If the bur is in the laryngeal pouch and cannot be removed with forceps. delay is indicated; if in the trachea, the inevitable consequences are explained, and an operation promptly advised.

Too often hope again intervenes her delusive voice and whispers, wait; the mother refuses to have her child's throat cut; the opportunity is lost, and perhaps a life is lost which might have been saved by a simple operation. There is scarcely an instance in the range of surgery where the patience of a physician is more tried by opposition to a rapid and comparatively safe operation. To a skilled surgeon, with his instruments and appliances at hand, opposition in such cases almost seems like manslaughter.

To the doctor in the country, in whose practice most of such cases occur, often without all the necessary instruments and assistants, without the support of consultation, and with a life hanging in the balance, the situation is peculiarly trying. In the city the surgeon returns in one or two hours, or can be summoned promptly, while in the country he has got to stay, to stay and do nothing except to give an emetic, a subcutaneous injection of morphine (a doubtful remedy), and perhaps more than all. the confidence his presence may inspire. His position is not enviable.

Now, it is just here that the important distinction by the attending physician or surgeon should be made when the air-passages are invaded by a foreign body. Is it in the laryngeal pouch, above the vocal cords, or is it in the trachea, and below the cords? If in the pouch and cannot for some reason be removed, and suffocation is not imminent, we can safely await developments, for by this time the patient is enjoying a season of rest. If in the trachea, notwithstanding the temporary relief, operation is called for, and the sooner the better.

Just here comes in the use of the laryngoscope, for with cocaine to paralyze the sensibility of the parts, we are insured a careful examination, and the position of the foreign body may be accurately defined.

Few country physicians have the instrument, and few are expert in its use. Now, in the absence of direct information by laryngoscopic examination, symptoms are our guide.

The symptoms of foreign bodies in the laryngeal pouch and in the trachea are at first nearly the same, subsequently they are different. By these signs we may determine with comparative accuracy whether it is in the one or the other. The differentiation is quite important.

If in the larynx, after the first one or two paroxysms of asphyxia are over they become less frequent, they last a shorter time, and the distress is not so great. The body has become stationary or only occasionally changes its position, and the pouch gets more and more tolerant of the intruding offender. Stridulous breathing is present throughout. Any fresh disturbance is the result of a new irritation, or is the effect of reflex action set in motion or aroused by a slight change of position of the foreign body.

The symptoms of a foreign body in the trachea differ somewhat. The spasms of asphyxia are more frequent, more painful, and more persistent. The inspiratory and expiratory currents of air constantly change the position of the body, which, ascending and descending, may finally drop into one of the bronchi and stop or lessen the air passing to that lung. There is also danger that in these movements it may become impacted in the chink of the glottis and death ensue.

According to the roughness or smoothness of the foreign body, and to its weight, more or less lymph and mucus will collect on its surface and thus increase or decrease the chances of displacement.

In both the voice and articulation are involved to a greater or less extent, and stridulous breathing is constant. Râles may be heard when the body is in the trachea, and the respiratory murmur may also be affected. Râles also are heard when the foreign body is in the larynx, but not to the same extent—they are modified. The foreign body being above the vocal cords, in the sacculus laryngis, and yet for reasons not removable, when no danger of suffocation arises it is safe to watch and wait. Nature will respond, and expulsion will probably take place in from one to ten days. The foreign body being in the trachea, operation is to be done promptly, because the vocal cords when irritated contract spasmodically, closing the rima glottidis, effectually preventing the egress of anything below, except under accidental or fortunate circumstances which rarely save the patient after many months of suffering.

The barrier formed by the vocal cords to the expulsion of a foreign body in the trachea is shown in numerous instances wherein after months the trachea is opened and it escapes through the artificial opening made, sometimes with considerable force, generally with a quantity of mucus and pus. When left to nature life is sometimes saved, but the patient usually succumbs to exhaustion or septicæmia.

The symptoms above described—differentiating foreign bodies in the larynx and in the trachea, and formulating the treatment which, in my opinion, should guide us in those cases where they cannot be removed at once, and are so difficult and perplexing to the surgeon—can be best illustrated by a detail of the four following cases, already referred to:

Case I.—December 19, 1889, Rosa N——, aged ten, of Summerville, S. C., was referred to me by Dr. Samuel Prioleau. While picking some cockle-burs from her father's clothes, on the 18th, she put one in her mouth and accidentally swallowed it. Urgent symptoms ensued. She passed a bad night and reported with her father at my office on the 19th. At this time the breathing was painful and she could only speak in a whisper. A solution of four per cent. cocaine was applied, and the bur was detected on the left side of the laryngeal pouch, in the vocal cord. The pain was so acute, in spite of the cocaine, the child so young, and the spasm of the larynx so great, that I was unable to remove the bur after repeated attempts with McKenzie's forceps. Each time they were applied, the prickly prolongations on the bur pressing into the cord produced such involuntary contractions that I was obliged to desist. I determined to wait till the next day, when, finding the œdema and swelling of the glottis on the increase, and attempting to remove it again and failing, she was put on the table for operation at St. Xavier's Infirmary, where she had been sent. Laryngotomy was performed under chloroform,

with antiseptic precautions. On passing in the forceps I felt the bur move, and at once noticed that the breathing was easier. After that I could not find it again, and concluding that it was swallowed when pushed up, the wound was closed. Two hours after, during the nausea following chloroform, the bur was vomited up, covered with lymph. Specimen exhibited. The wound healed by first intention, recovery was prompt and without note. The voice was entirely restored in about two months.

Case II.—September 19, 1890, Jennie S——, colored, aged seventeen, Sullivan's Island, S. C., was sent to me by Dr. P. G. De Saussure with cockspur in larynx. The voice was husky, and she complained of a sticking sensation when swallowing. She had taken an emetic of alum and repeated it without success. When I saw her there were no violent symptoms of dyspnœa; the bur could be seen on right vocal cord, in the laryngeal pouch. I was unable to remove it, owing to spasmodic contractions whenever forceps were applied. On the 20th, there still being no bad symptoms, determined to wait after spraying the throat with borax, and then with cocaine. On the 21st and 22d the same treatment was followed. On the 23d the bur was expelled covered with lymph. Specimen exhibited. The voice was restored in about two weeks.

Case III.—December 14, 1890, Maude W——, aged twelve, Pleasant Hill, S. C., was sent to me by Dr. S. Beckham. On the 13th, while picking burs from her father's clothes, she put one in her mouth and accidentally inhaled it. Difficulty of respiration and loss of voice ensued as usual. One day after, when I saw her, respiration was comfortable, voice only a whisper, but swallowed milk with comparative ease.

On the 15th bur was visible in pouch, on right cord. Tried to remove it under cocaine but failed, so sent patient to the hospital, where she was carefully watched and emetics of hot water and mustard were ordered, with soothing applications. The bur was expelled on the fourth day, covered with lymph. Specimen exhibited. Recovery of voice was complete in less than a month.

Case IV.—January 24, 1891, Norman I——, aged nine, Walterboro, S. C., was sent to me by Dr. C. H. Brown Lee. Three days before, while playing with bur in mouth, suddenly inhaled it. The usual symptoms ensued. Dr. Lee attempted to get it out. Loss of voice soon followed. On the 24th, when I examined him, the cords were intensely congested, but their action was normal, and I failed to detect any foreign body. Concluding that it had been expelled or swallowed, the child was sent home and given a soothing expectorant mixture, and told to gargle with hot water.

Recovery took place in a few weeks and voice returned.

In addition to the above, I take the liberty of referring to two cases reported by Dr. John E. Pendleton, of Hartford, Ky., in the "Transactions of the Southern Surgical and Gynecological Association," vol. iii.

In the first a young man accidentally inhaled a cocklebur, and a sudden inspiration carried it into the windpipe. When the doctor saw him, two hours after, he was in a terrible condition, countenance anxious, pulse rapid, respiration labored, and aphony complete. Tracheotomy was proposed, but the mother refused to consent. After three months of dreadful suffering, with hectic fever, night-sweats, purulent expectoration, and extreme emaciation, he coughed up the bur and recovered.

In the second, a young man consulted him with a bur in his trachea He refused tracheotomy, went home, and had a similar experience to that of the preceding case, except that the bur was not expelled for five and a half months from the time it was inhaled.

These are the only cases of this peculiar kind of foreign body invading the air-passages I have seen or heard of. It would appear that in the larynx they are expelled soon and give comparatively little trouble. In the trachea they remain a long time and cause an endless chain of difficulties, sufferings, and complications.

70 Hasell Street.

THE KNEE-JERK.

By JOHN FERGUSON, M.A., M.D. L.R.C.P.,

DEMONSTRATOR OF ANATOMY, UNIVERSITY OF TORONTO MEDICAL COLLEGE, AND LECTURER ON NERVOUS DISEASES IN THE SUMMER SESSION.

That the knee-jerk is a symptom of great importance none now doubts. Its presence in normal or exaggerated degree, or its absence, requires at the hands of every clinical observer due consideration. Since the knee-jerk was first noticed, there have been many theories advanced to explain its nature. It has been held by some to be purely of muscular origin. This, however, no one now entertains. Then, again, it has been regarded as of spinal origin exclusively. This, in man, has also been greatly discredited by careful investigations made on cases of increase and loss of this phenomenon. Then there are those who regard it as of spinal origin—that the spinal centres are under the control of the cerebrum in such a way that the jerk is inhibited by it; when by injury or disease the brain loses its control over the spinal centres, these latter act with undue energy, and the jerk becomes, in consequence, an exaggerated one. There are those, again, headed by J. Hughlings Jackson, who regard the energy as coming from the cerebellum in the first place, and stimulating the spinal centres, and that these latter are inhibited by the cerebrum. To each of these views I shall direct some remarks during the course of this article.

That the knee-jerk does not depend upon the spinal centres alone, the careful analysis of cases seems to show clearly. If neither the cerebrum nor the cerebellum supplied an energy or influx of force to the spinal cord for the purpose, then, when the cord becomes separated from them, we would still find the knee-jerk intact. Indeed, according to many, if the lumbar enlargement remains uninjured, the knee-jerk must be present in greater degree than before the separation took place. Is this in accordance with facts?

In one case, a boy, seventeen years of age, there was a very sharp angular curvature at the fourth dorsal vertebra. At first the knee jerk was exaggerated, but later on it gradually disappeared, and finally became wholly extinct. There was no atrophy, beyond that of disuse, in the muscle dependent upon the lower part of the cord; nor was there reaction of degeneration. There were both complete paralysis and anæsthesia. The patient died of pulmonary phthisis. The autopsy revealed the important facts that the cord was completely pulpified at the situation of the curvature, and that there was no coincident softening of the lumbar enlargement.

Another case bearing upon this point is one of fracture dislocation. The displacement was between the second and third dorsal vertebræ. The knee jerk at once disappeared, and remained absent for eighteen months. The bladder reflex was fairly good. The lumbar enlargement was normal in every respect, except the descending degeneration found in the pyramidal tracts. There was no muscular atrophy, nor reaction of degeneration. The patient was annoyed with erections. There was no rigidity or spastic condition of the legs.

In another case of dislocation of the sixth and seventh cervical vertebræ there was absolutely no knee-jerk. None ever appeared, though the patient lived for nearly five weeks—a time quite sufficient to cause the jerk to appear, if due to degeneration merely in the pyramidal tracts. The bladder acted fairly. There were erections. No reaction of degeneration or atrophy. The cord was thoroughly pulpified and destroyed. In these three cases there was no ankle clonus.

In the above cases it is very clear that the cord was completely severed from both cerebrum and cerebellum. If the knee-jerk and ankle clonus depend upon the spinal cord, and are only inhibited by the brain, then these phenomena would have been increased in these cases. But we find that such was not the case. When the cerebrum and cerebellum were detached from the cord, the latter in itself did not possess the power of maintaining

the muscular tone upon which the knee-jerk and ankle clonus depend. It becomes very patent the knee-jerk is something more than a spinal reflex.

When we turn to a class of cases with which all are familiar, namely, those where the cerebral influence on the spinal cord has been lost through disease or injury (it matters not whether by a hemorrhage, an embolism, a primary sclerosis, or a blow on the head) the effects are the same—the inhibitory control of the cerebrum is removed, and, as a consequence, the spinal centres, let loose from this inhibition, act overmuch, and there are both exaggerated knee-jerk and ankle clonus. We have just seen, however, that where both cerebrum and cerebellum are cut off from the spinal centres no such state of things exists.

It is not necessary to record cases in this group, as they are so common and well known. One, however, may be of interest. A lady, aged fifty two years, had an attack of hemiplegia affecting the right arm and leg, with marked increase in the knee-jerk. Just thirteen years afterward she had a second attack, affecting the left arm and leg, with hemianopsia. Six weeks after the attack there was great increase in the knee-jerk, even rectus clonus. The loss of sensation was complete, and the paralysis of the fullest possible extent. Here is a case where all cerebral influence was withdrawn from the left side, and yet the tone of the muscles still continued, and the knee-jerk was greatly increased. Certainly the source of energy to the spinal centres is not of cerebral origin.

In his valuable work on nervous diseases, while speaking of tumors of the cerebellum, W. R. Gowers remarks that, "in the same cases the knee-jerk cannot be obtained; its loss is usually constant; a slight movement can be elicited at times, and at times none. We are not at present able to explain this curious symptom" (page 717, American edition). I think this can be readily explained when we look in the right direction. That the reflex at the knee depends on the myotatic irritability there is no doubt. It seems equally clear that this irritability is necessarily associated with the normal healthy condition of the nervous arc of afferent and efferent fibres connected with each other in the spinal cord. But, while this is true, we have seen that there is something more needed than this purely spinal arc. We have the true explanation in the cerebellum.

On this subject Charlton Bastian has done most excellent work. That his ground has been well taken experience will prove. He has for some time advocated that if there be a total transverse lesion of the cord above the lumbar enlargement there will not be any knee-jerk. Now I have just recorded three such cases. The lesion was complete, and the absence of the knee-jerk was just as complete. I have also called attention to that group of cases where cerebral influence is cut off, with the result of increasing the knee-jerk. I shall now mention two cases of cerebellar disease, with complete loss of this phenomenon.

The first case was that of a man, forty-five years of age, who had suffered for some time with severe occipital headache. He had marked cerebellar titubation. The diagnosis of cerebellar tumor was made. He went to Edinburgh and consulted, I think, Sir P. H. Watson, who thought also that there was a tumor in the cerebellum. This was confirmed after death. The point of interest in this case, so far as this paper is concerned, is the fact that the knee-jerk gradually disappeared, and, for at least six months prior to death, could not be obtained on any occasion, by any method of testing. The tumor was tubercular.

The second case, a girl aged eleven, was diagnosed to have a cerebellar tumor. There was pain, vertigo, vomiting, titubation, mental failure, and difficult articulation. The urine was 1.031, contained some sugar, but no albumin. The knee-jerk was absolutely abolished. There was no ankle clonus. The bladder and rectum were impaired, but not to a marked extent. The autopsy showed the existence of a glioma in the cerebellum, involving the left hemisphere and middle lobe completely, and the right hemisphere to about one-half its size.

These two cases go to show most conclusively that Hughlings Jackson is right when he contends that the knee-jerk and muscular rigidity is due to "cerebellar influx." In the three cases of transverse lesion in the cord, recorded in this paper, this influx was cut off from the cord below the lesion, and consequently there was neither knee-jerk, ankle clonus, nor muscular rigidity. In the two cases of tumor in the cerebellum the power of the cerebellum to influence the lower spinal centres was destroyed through the existence of the tumors. We may therefore safely infer that the integrity of the cerebellum and its healthy connection with the spinal centres are the real causes of the deep reflexes. This throws a flood of light on another question, namely, that the cerebellum has much to do with the maintenance of the equilibrium of the body by means of muscular efforts put forth in accordance with visual, auditory, and tactile sensations.

The truth of these views is of very great importance. In the case of a transverse lesion of the cord, above the lumbar enlargement, they would prove that the injury was a complete one. Or, to put the question in another form, if there were an injury to the spinal cord, and that, after the shock had passed off, there were absence of knee-jerk, ankle clonus, and muscular rigidity, the injury may be taken as a complete one. Further, if there be loss of the knee-jerk, and deficiency of muscular tone, while there are no evidences of disease in the spinal cord, our attention should at once be directed to the cerebellum, as it has been just shown that these symptoms may be lost through disease in this organ. They have an important bearing on prognosis. Grant that there is an injury to the cord, and that there is neither knee jerk nor ankle clonus, the prognosis is very bad, because the cord must be thoroughly crushed or pulpified. Operative treatment in such a case would be contraindicated.

In the exaggerated knee jerk that follows epilepsy we see this same principle upheld. The cerebral cortex is exhausted by the discharge, and as a result does not inhibit the spinal action, which becomes excessive from the cerebellar influx. Elsewhere I have given an account of four cases of procursive epilepsy. In one of these cases I had a good opportunity of testing the condition of the knee-jerk. There was not any past epileptic increase. This fact, along with others, led me to suspect that procursive epilepsy is due to a discharge, beginning in the cerebellum, and causing the procursion, along with derangements of equilibrium, and the absence of the knee-jerk, instead of its increase after the attack. The discharge in the cerebellum causes its exhaustion, so that the spinal cord does not receive the influx from this source, while the cerebrum goes on inhibiting all that the easier. When the discharge is cerebral, inhibition is weakened and the reflex increased; when the discharge is in the cerebellum, the influx is weakened and the reflex lost.

Prescriptions and Chirography. — Physicians have always enjoyed the reputation of writing the most illegible hands of all bodies of business or professional men, and many stories are current of meaningless scrawls being presented to drug-stores and being filled as prescriptions. But a change is coming, at least a beginning of a change has been made, for in Austria the Minister of the Interior has ordered that hereafter physicians must write their prescriptions in a legible hand, and must add thereto clear and explicit directions as to how and when the medicine is to be taken.

Attempt to Kill a Doctor.—A physician in Versailles, Ky., was rudely awakened the other night by the explosion of a bomb, which had been placed against a door of his office. The building was nearly destroyed, but fortunately the physician and the other inmates escaped with slight injuries.

THE OPERATION OF GRATTAGE FOR TRACHOMA.

By W. B. MARPLE, M.D.,
NEW YORK.

For some time past ophthalmologists the world over have been endeavoring to find a method of treatment for trachoma which would result in a more speedy cure than methods already employed. With this end in view Professor Sattler, of Prague and Leipsic, has curetted the trachomatous conjunctival surface; Professor Galezowski, of Paris, has excised the forming fold; various devices as those of Professor Noyes and Professor Knapp, for squeezing out the contents of the trachomatous follicles, have been employed; and more recently what is known in Paris as grattage has been employed, possibly more frequently by Professor Abadie's assistant, Dr. Darier, to whose kindness and courtesy in facilitating his study of the operation and its results the writer is especially indebted.

Without endeavoring to institute a comparison between the relative merits of these different forms of treatment, other than to observe that the method under discussion seems to be applicable to a greater variety of cases than the others mentioned above, the writer ventures to describe somewhat in detail this "grattage," which is a more or less extensive scarification of the trachomatous surface of the lids. This scarification was used in trachoma many years ago and subsequently abandoned. As at present employed, however, it is combined with a vigorous scrubbing of the scarified conjunctival surface with a solution of sublimate 1 to 500.

The simple instillation of cocaine is insufficient to control the pain, which is apt to be quite severe. It is, therefore, much better to etherize the patient.

Technique.—Complete eversion of the lid, so that the most distant portion of the forming conjunctivæ is brought plainly into view, is essential to the success of the operation. This eversion is accomplished by grasping the edge of the lid with a pair of catch dressing-forceps, the blades running along the edge of the lid, and then turning the forceps in their own axis, thus rolling or folding the lid outward around the forceps until the most distant portion of the forming is in full view. If the palpebral fissure is very narrow, it is of advantage as a preliminary to enlarge this by an external canthotomy. If necessary the lower lid may be drawn down out of the way by a lid-retractor in the hands of an assistant. Then with a small sharp scalpel, or Desmarre's scarificator (some employ a scarificator with two or three parallel blades), the trachomatous surface is scarified by numerous incisions close together and parallel to the margin of the lid. A few incisions are then made at right angles to the first, and then this bleeding surface is thoroughly scrubbed with a stiff tooth-brush dipped into a sublimate solution 1 to 500. The scrubbing is somewhat vigorous, and is repeated two or three times, the brush being repeatedly moistened afresh by dipping in the solution. Then the lid is, so to speak, untwisted by turning the forceps back, thus allowing the scarified surface to slip back out of sight and bringing into view a fresh portion of conjunctiva or trachomatous surface nearer the margin of the lid. This is scarified in like manner, and subsequently brushed with sublimate, and so on till the whole of the affected lid has been treated in like manner. Then we procced in the same way with the lower lid, and then with the other eye according to the necessities of the case. After cleansing the eyes a plaque of gauze moistened with sublimate solution 1 to 2,000 is laid over the lids, covered with absorbent cotton, and a bandage is applied. The latter is usually removed permanently on the following day.

Subsequent Treatment.—Beginning the second or third day after the operation (depending on the amount of reaction), the lids are daily everted carefully and washed with a pledget of absorbent cotton dipped in sublimate solution 1 to 500, rubbing the surface sufficiently to remove all discharge and membranous shreds. The cases are allowed to leave the hospital usually in four to six days, returning daily as out-patients to the clinic for from four to six weeks. After three or four weeks, if there is still considerable discharge, a solution of nitrate of silver (5 gr. ℥ j.) is substituted for the sublimate and brushed over the conjunctival surface. In the majority of cases no futher treatment is employed after six to eight weeks and the patient is discharged cured.

Reaction.—The amount of reaction following the operation varies considerably. Of course, there is some swelling of the lids for several days, and not infrequently some subcutaneous ecchymosis of the lids. Occasionally considerable œdema is observed, which subsides in a few days without any special treatment, though ice applications may be employed. At the end of eight or ten days, and often sooner, the external appearance of the lids is about as it was before the operation, while the characteristic rough granular appearance of the conjunctiva becomes rapidly more and more smooth.

Extent of Scarification.—The extent of the scarification will be determined by the amount of the trachomatous swelling. Over the forming portion, when the swelling is apt to be considerable, the scarifying will be extensive, incisions close together and deeper; on the other hand, over the tarsus, especially of the lower lid, there may be very slight, or even no trachomatous swelling, requiring accordingly slight or no scarification. The judgment and experience of the operator will decide this.

As an adjunct to the scarification, where there is much vascular pannus the loop of vessels may with advantage be divided just outside of the corneal margin by the point of the galvano-cautery. This may expedite the clearing up of the cornea, though it is not essential.

To decide whether the treatment is followed by much scar-tissue on shrinking it will be necessary to observe the cases for a longer period. Aside from this consideration, the results in rapid return of the conjunctiva to a comparatively healthy condition, the clearing up of corneal opacities, pannus, etc., are certainly remarkable, and the method is well deserving of a more extended trial.

A number of cases have been recently operated on in this manner, at the New York Eye and Ear Infirmary, Dr. John E. Weeks.

The operation has been employed now for some time, in Paris, by Professor Abadie and assistant, Dr. Darier, Professor Panas, Professor Wecker, and others.

Note.—To show that the above treatment gives as gratifying results in New York as in Paris, brief notes of two cases seen during the past week by the writer are appended. The history of the two cases is given by the kind permission of Dr. Weeks in the first case, and of Dr. Gruening in the second.

No. 1.—Girl, aged eighteen. Marked trachoma of two years' standing of the left eye, with considerable discharge.

August 8th. Grattage under ether. Patient treated as an out-patient at the New York Eye and Ear Infirmary, returning home after recovering from the effects of the ether. But slight reaction.

August 15th. No sign of trachoma.

August 19th. Patient ceased coming to clinic, as lids were smooth. No discharge.

October 10th she appeared at the clinic of the New York Eye and Ear Infirmary, showing a result as nearly perfect as one often sees Nothing about eyes would indicate that anything had ever been the matter with them. No sign of any scars at all, and lids smooth and pliable.

No. 2.—Boy, aged thirteen. Has had trachoma, and for two years past corneæ were so opaque and photophobia so great that boy could not see to go alone. Before operation condition was deplorable. On account of corneal opacity no iris could be seen. In last week of September grattage was done by Dr. Gruening at Mount

Sinai Hospital. Two weeks subsequently no photophobia, lids becoming rapidly smooth. But the change in condition of the cornea is most surprising. This has cleared so that iris and pupil can be readily seen, and boy now sees to go around without difficulty. A few nebulous maculæ still left in cornea, which are becoming rapidly less. Improvement continues from day to day.

These were both chronic cases of over two years' standing.

29 West Thirty-first Street, October 20, 1891.

Progress of Medical Science.

Pseudo-Tuberculosis.—Professor Hayem reports this case: The patient was a youth, seventeen years of age, without any hereditary history of tubercle, who had had typhoid fever at the age of thirteen. For several months prior to coming under observation a slight bronzing of the skin was noticed. This was followed by general malaise, with vomiting and all the signs of a febrile gastric affection. The temperature remained raised for several days, and then dropped. The patient then appeared to fall into collapse. The extremities were cold, temperature subnormal, and he complained of vague muscular pains and extreme weakness. A diagnosis of gastro-enteritis was made, but no cause could be discovered. The tongue was pale and furred; vomiting became more frequent; there was great thirst; the stools were normal, but sometimes diarrhœa occurred. Liver, spleen, and lungs normal; cerebral symptoms absent. The patient eventually died of cardiac collapse. Owing to the increase in the bronzing of the skin the diagnosis of Addison's disease was finally made.

At the autopsy the right suprarenal body was normal, but the left was found to be transformed into a grayish mass; the glands of the neighborhood were normal The grayish mass was softened in the centre, which was surrounded by round cells. No tubercular nodules could be seen, giant-cells were absent, and the search for tubercle bacilli was unsuccessful; but, on the other hand, the bacilli of pseudo-tuberculosis were found. The stomach was normal. The intestines were somewhat inflamed, especially around Peyer's patches. The follicles, both isolated and agminated, were enlarged, and in them the characteristic bacilli were found; the blood also contained them. The lungs were normal. Cultures made from the blood, the intestine, and all the abdominal organs produced similar bacilli to those obtained from animals which had died of pseudo-tuberculosis. Inoculation made on animals from the cultures produced the disease. This is characterized by the formation, especially in the abdominal organs, of a condition which to the naked eye is precisely similar to miliary tubercle. Small nodules are formed, which under the microscope are seen to consist of collections of small round cells, surrounded by cells more epithelial in character; giant-cells are rare. The bacilli are extremely difficult to stain in the tissues, but cultures are easily made. The organism grows well on all the ordinary media, especially nutrient gelatine. In forty-eight hours at the ordinary temperature a luxuriant growth results. The bacilli are short, thick rods, appearing at first sight almost like diplococci. Under a high power, however, the rod formation is undoubted. The bacilli exhibit a great tendency to run together into rods; in fact, some authors have declared that the organism is polymorphous. Animals inoculated with the fresh culture die in from ten to fourteen days. Intra-venous injections produce death in about forty-eight hours, without the formation of the characteristic lesions.—*Revue Générale de Clinique et de Thérapeutique.*

that congestion of the left kidney occurs much more frequently than congestion of the right kidney or of both kidneys. For emphasis, not exactness, let us say it occurs twenty times as often in the left as in both. 3. Practitioners who observe closely will have noticed that the frequency with which inflammation, and its somewhat frequent sequel, abscess, occurs in the left kidney as compared to the right, or to both, is in about the same ratio. 4. Such will have also observed that tumors, commonly a result of congestion or obstruction, occur more frequently in the left kidney than in the right.

About four years ago I first took up this study of the left kidney. It came about in this wise: A practitioner up the Hudson diagnosed congestion of left kidney in the case of Henry Ward Beecher, who had been taken suddenly ill at his country home. A city editor referring to this diagnosis threw a handful of exclamation points after it, in derision, in his journal. I have pursued this study attentively since and find this lesion of frequent occurrence—one of the most frequent ailments of the human body.

About three years ago a patient, a man aged about fifty-five, came to me with matter flowing copiously from the left side of the scrotum, the pus being generated in and the result of abscess of the left kidney. In eight weeks' practice last summer I saw seven cases of disease of the left kidney, one having resulted in abscess, the right kidney being apparently normal in all these instances.

MATERNAL IMPRESSIONS.

The Value of Palpation in the Diagnosis of Tuberculosis in Children.—Mirinescu, in a carefully prepared paper on this subject, refers to the fact that positive signs of tuberculosis in infants and young children are lacking, and we are frequently obliged to make a diagnosis of probability even when the disease is well advanced. When active inflammation complicates the tubercular process the diagnosis becomes at times impossible. It is impossible to distinguish a simple from a tubercular bronchopneumonia by physical signs alone. The diagnosis of abdominal tuberculosis is equally difficult, especially in the earlier stages. A diarrhœa in an ill-nourished child may be simple and due to bad feeding, or it may be due to tuberculosis. The physician who is guided by local symptoms only exposes himself to the danger of making grave errors. It is only by a thorough examination of the whole body that anything like a positive diagnosis can be reached, and every symptom and sign must be taken into consideration. Some years ago Hutinel observed that the majority of children in a hospital presenting symptoms of tuberculosis also had general adenitis, and he regarded this as a sign of considerable value. Legroux has also pointed out the fact that these enlarged glands are tubercular in character. Children predisposed to tuberculosis are very frequently pale, anæmic, and subject to alternate constipation and diarrhœa, with variable appetite. The skin is flabby and evidences of bronchitis are usually present. Groups or chains of small glands may be felt just beneath the skin in the groin, the armpit, and the cervical region under the jaw or behind the ear. They are hard, and upon palpation give the sensation of lead-shot under the skin, being movable and free from adhesions. They are peculiar in two respects: 1. They are so widely distributed as to form a general adenitis, and are found in regions where there is no other trace of tubercular involvement. 2. They never change in size or consistence. In most of the cases presenting this condition, examination has revealed other lesions and tubercular bacilli in abundance. It cannot, however, be positively said that every child presenting this general adenitis is tuberculous, but with other symptoms, even if vague, its presence is very strong evidence of tuberculosis. Children frequently become tuberculous slowly, showing little evidence of the disease except by a general poor condition and disease of the lymphatic system. Suddenly a bronchitis or whooping-cough develops, to be followed by broncho pneumonia, from which the child dies. The autopsy reveals tubercular lesions of long standing. General adenitis in syphilis is rare, and appears to be due

THE OPERATION OF GRATTAGE FOR TRACHOMA.

By W. B. MARPLE, M.D.,

NEW YORK.

For some time past ophthalmologists the world over have been endeavoring to find a method of treatment for trachoma which would result in a more speedy cure than methods already employed. With this end in view Professor Sattler, of Prague and Leipsic, has curetted the trachomatous conjunctival surface; Professor Galezowski, of Paris, has excised the forming fold; various devices as those of Professor Noyes and Professor Knapp, for squeezing out the contents of the trachomatous follicles, have been employed; and more recently what is known in Paris as grattage has been employed, possibly more frequently by Professor Abadie's assistant, Dr. Darier, to whose kindness and courtesy in facilitating his study of the operation and its results the writer is especially indebted.

Without endeavoring to institute a comparison between the relative merits of these different forms of treatment, other than to observe that the method under discussion seems to be applicable to a greater variety of cases than the others mentioned above, the writer ventures to describe somewhat in detail this "grattage," which is a more or less extensive scarification of the trachomatous surface of the lids. This scarification was used in [illegible] form. By removing the crystals with a pipette and subjecting them to the microscope, they are seen to consist of yellow needles, often in groups, radiating from a central point. If there be a moderate amount of sugar present, the yellow zone is quite visible to the naked eye. The reaction is said to be more marked if the fluid is boiled before the chloroform is added, but in this case care must be taken to allow it to cool again, for if the chloroform is added while hot an explosion might occur. This test is extremely delicate, and shows the presence of sugar where Fehling's test has failed.—*Centralblatt für klin. Med.*

Clinical Department.

OLIVE OIL AND GALL-STONES.

By DAVID Y. WINSTON, M.D.,

RUSSELLVILLE, KY.

In the issue of the MEDICAL RECORD of October 24th, I see an editorial giving the results of an analysis of fifty-four cases of biliary colic by Drs. Mays and Bloom, of Philadelphia. The editor does not seem to have much faith in the oil, nor do I think a careful look into these cases would justify much faith. Physicians are apt to mistake the bodies passed after taking the oil for gall-stones, or to accept the word of the patient or family as to the fact.

In fifty-one cases they think there were favorable results from its use. I will simply give my own experience with it, and cases that have fallen under my observation. In the first place, sweet oil taken in large quantities (one pint to one quart in twenty-four hours), sometimes will, sometimes will not, cause an evacuation of globular, greenish, or dark bodies, resembling gall-stones. Some of these are so hard as to give a sound on striking the bottom of the chamber, when ejected forcibly; others are of less consistency. These bodies are fatty in nature and probably colored with the bile itself, or its coloring matter.

After the writer took (within the space of two hours) one pint of pure olive oil, there was no effect, no disturbance of stomach or bowels, nor any "gall-stones."

At another time, a like quantity brought a considerable (twelve or fifteen) number, with no other symptom than a little gastro-intestinal disturbance. I believe their appearance or not is due to whether or not the digestive organs are incapable, or capable, of properly assimilating the oil. Large amounts would therefore be more likely to cause this formation in a healthy man. That they were oily there is no doubt, for they melted enough to grease paper on moderately warming, completely on stronger heat, burnt like oil, were greasy to touch, and were freely soluble in ether.

One case came under my observation not long since, in which the woman for several years has had attacks like the passage of gall stones, but no stone has ever been found in the passages, though searched for by her physician. Nothing but morphine and atropine given hypodermically in full doses gave ease, the attacks lasted from a few hours to a day or more. No physical signs give evidence as to its nature, there being no jaundice nor enlargement of gall-bladder perceptible. At the suggestion of outsiders she took sweet oil in large quantities. The next day she passed a number of bodies precisely like those I have described, some as large almost as a pigeon's egg, some smaller. The passage was attended with pain, griping, etc., and she had a slight diarrhœa following. The bodies passed were physically and chemically, as far as I could tell, identical with those first described, and a little harder than wax when cold.

She thought she was better for a while, but had other attacks and repeated the oil with same results. She is, however, now, in spite of oil taken on several occasions, just as bad off as before taking a dose. Another case, almost similar, has also been observed. The woman had an attack (the first and only one) which was diagnosed gall-stone passing along duct. Here the oil was given by the physician, also anodynes were administered. The oily bodies were passed, she got easy, and was said to have passed a number of stones, and olive oil was praised as the great specific. On examination they proved to be nothing but "oil-stones."

Ease of pain occurred when the opiate had taken effect, and was attributed to the oil. I have examined the "stones" brought by several physicians after the administration of oil, and have in no instance found a single true stone. Some of the patients were, some were not, afterward troubled with attacks, but as this freedom from attacks seemed to be no more common than seen where oil was not used, no deductions could be drawn showing its benefit. If the oil is a cholagogue, given in continuous small doses it might act as a preventive, or during an attack, as any other bile-stimulating drug, help force the stone along the duct. Otherwise from this, I fail to see how it can do the least good, nor do I think the testimony given by careful men will be in its favor.

PEROXIDE OF HYDROGEN IN TYPHOID FEVER.

By F. H. WIGGIN, M.D.,

NEW YORK.

Having had good results in using peroxide of hydrogen locally in diphtheria and tonsillitis, and in infected wounds, it occurred to me, when a case of typhoid fever came under my care, during my summer practice, that this remedy might be beneficial, it being the most powerful non-poisonous germicide we possess. On August 24th I was called to see Abby M——, who gave a history of having been ill for a week with fever and diarrhœa. On examination I found a characteristic case of typhoid fever, with temperature 104½° F.; pulse, 130; sore spots, abdominal pain, tympanites, diarrhœa, and mild delirium. I prescribed one ounce of fifteen volume peroxide of [illegible] phobia so great that boy could not see to go alone. Before operation condition was deplorable. On account of corneal opacity no iris could be seen. In last week of September grattage was done by Dr. Gruening at Mount

26th had had one movement; temperature, 102° F.; pulse, 104; less tenderness in abdomen, and pain in head diminishing. On the 27th, temperature, 100½° F.; pulse, 98; no movement, tympanites disappeared, and head, though still weak, clearer. On the 29th, temperature, 99¼° F.; no movement. On the 30th, temperature normal; pulse, 84; formed movement. The case now went on uninterruptedly to recovery, with nothing further of interest to report. On the 9th of September I discontinued my visits, the patient being discharged cured, though weak.

One swallow does not make a summer, but I report this case, hoping that someone who has larger opportunities for treating typhoid fever may take up the suggestion and let the result be known. The remedy is perfectly harmless, easy to take, and apparently was of very great value in this case.

THE WEAK LEFT KIDNEY.

By T. J. HUTTON, M.D.,

ST. PAUL, MINN.

It is not stating a news-item to say that some parts of the human body are anatomically and functionally feebler than others: for example, the various hernial sites are acknowledged weak points. Indeed, in the dexter-handed the entire left side of the body is less developed than the right side; and what is true of the left side as a whole may also be true of its various parts. Of some of its parts it is already admitted to be true; accident indemnity companies pay more for the loss of a right limb than for the loss of a left, based upon its greater usefulness. Their rule is to pay $2,500 for the loss of a right hand and $1,500 for the loss of a left hand. The earlier editions of "Gray's Anatomy" used to harp on the absence of valves in the left external saphenous vein, which condition in scurvy and kindred ailments, attended by hydræmia, stasis, and effusion, induced a soggy swelling in the anterior aspect of the left thigh. In Russia they give this swelling a distinct name, as though it constituted a distinct disease. This swelling never occurs on the right side.

The object of this paper is, not to advance the theory that the left kidney is feebler than the right one, but to adduce ample proof, anatomical and clinical, that such is the fact; and that in the entire field of medicine no fact is more obvious. As to anatomical peculiarities there are none in the kidney itself, but there are several in its vascular outlet which may and do injuriously affect the kidney itself.

Anatomical peculiarities of the left renal vein are: 1. The left renal vein is longer than the right. 2. It passes in front of the aorta. 3. It receives the left spermatic, the left inferior phrenic, and generally the left supra-renal veins. 4. It opens into the vena cava a little higher than the right.

Each of these peculiarities of the left renal vein—that it is longer than the right; that it passes in front of the aorta, which the right does not; that it receives several other veins which the right does not, and that it enters the vena cava higher than the right—renders the left kidney more liable to obstruction than the right.

The clinical peculiarities of the left kidney are: 1. Excepting the single symptom of belly-ache, which afflicted Mr. Stiggins so much, and which, in the language of sister Hemans, has not only all seasons but all persons for its own, perhaps no symptom is more frequently met with than pains and aches in the left side and left lumbar region, or, in other words, in the region of the left kidney. 2. Every experienced practitioner must have observed that congestion of the left kidney occurs much more frequently than congestion of the right kidney or of both kidneys. For emphasis, not exactness, let us say it occurs twenty times as often in the left as in both. 3. Practitioners who observe closely will have noticed that the frequency with which inflammation, and its somewhat frequent sequel, abscess, occurs in the left kidney as compared to the right, or to both, is in about the same ratio. 4. Such will have also observed that tumors, commonly a result of congestion or obstruction, occur more frequently in the left kidney than in the right.

About four years ago I first took up this study of the left kidney. It came about in this wise: A practitioner up the Hudson diagnosed congestion of left kidney in the case of Henry Ward Beecher, who had been taken suddenly ill at his country home. A city editor referring to this diagnosis threw a handful of exclamation points after it, in derision, in his journal. I have pursued this study attentively since and find this lesion of frequent occurrence—one of the most frequent ailments of the human body.

About three years ago a patient, a man aged about fifty-five, came to me with matter flowing copiously from the left side of the scrotum, the pus being generated in and the result of abscess of the left kidney. In eight weeks' practice last summer I saw seven cases of disease of the left kidney, one having resulted in abscess, the right kidney being apparently normal in all these instances.

MATERNAL IMPRESSIONS.

By F. C. HERR, M.D.,

OTTAWA, KAN.

Apropos of the discussion in the Medical Record, I wish to contribute my mite in support of the theory of "Maternal Impressions." In point of fact, however, it is no longer a theory that the mother may transmit, not only mental characteristics to her progeny, but physical impressions as well. It is matter of common knowledge that young married women looking forward with ardent pride to prospective motherhood, will keep themselves impressed with ideal faces by decorating the bed chamber walls with pictures of handsome children. I am quite sure I have seen a striking resemblance between the children of these mothers and the object of their admiration.

But two most remarkable cases—one quite recent—have come to my knowledge, and I desire to record them. The recent one occurred in this city. A lady—six weeks advanced in pregnancy—was sued before a justice of the peace by her servant girl for non payment of wages. The lady received a notice to appear at the office of the justice. This was new experience to her, and as she herself stated, it almost frightened her to death. She went. The justice, whom I know, has a cleft palate. His articulation is most difficult to understand, and his manner of speech, when you do not know him, rather repulsive.

After returning home from his office for weeks this experience was on her mind, and she said she could hear the squire talk all the time. A child was born to her, and the physical conformation of the palate, arches, and roof of the mouth was the counterpart of that of the justice.

The second case is even more interesting and remarkable. The husband of a lady who was enceinte returned home from a day's fishing and brought with him a frog whose head had been much lacerated by the fish-hook catching in it. Thinking to have some sport, he placed the frog upon the floor just behind a chair occupied by his wife, and left it there for her to see. Soon she arose from her chair, turned about and beheld the frog, and fainted away. At term she gave birth to a child with a frog's head, the exact image of the one upon the floor. This is one of the most remarkable examples of maternal impression that I have knowledge of. The case occurred in the practice of Dr. George Hirsh, of Harrisburg, Pa. To him I am indebted for it.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, November 28, 1891.

RACE AND DISEASE.

CERTAIN races of mankind possess greater vitality and tenacity of life than others. Pre-eminent among the vital races stands the complex Anglo-Saxon, who seeks the north pole without fear, penetrates the heart of Africa, plants business enterprises upon the equator, and carries commerce into every degree of latitude, regardless of climate. Scandinavian, Frank, and Teuton also possess a similar spiritual and physical endurance that conquers circumstance and overcomes the forces of nature. The Slav, the Latin, and the despised Turk share it in part.

Causes of disease that slay thousands of those subject to them, but who through habit lack vigor of constitution, which is always the best safeguard, pass lightly over hardier or temperate-zone races. Thus is explained the comparative immunity, during the great plague in Alexandria in 1835, of French, English, Russian, and German residents. Though exposed in the most open manner, it is said they suffered only in the proportion of five per cent., while Arabs succumbed at the rate of fifty-five per cent.; Malays, sixty-one; negroes and Nubians, eighty-four per cent. Among certain American Indians there is one death in every 26.23 inhabitants, and this not due to the cruelty of the unfeeling white man.

Among less hardy peoples, the inhabitants of the earth in whom inherent vitality is of a low order, the readiness to lie down and die upon slight provocation seems a cowardly kind of business to others trained in habits of real grit. The plucky races of mankind are determined to pull through, to fight disease as though it were an attacking enemy, to recover to please friends, spite rivals, foil foes, or complete some task as yet unfinished. Some impulses from the organs of thought and will materially affect the rest of the nervous system, the heart, and secretions. The weaker races die as easily as falling asleep, die from "pure cussedness," as the sailors say. The late surgeon of R. Y. S. Sunbeam, Bernard Hoffmeister, records interesting experiences among the natives of East Africa. Their apathetic dependence on fate, and its consequent mental and physical inertia, are best overcome by alcohol. They are so unaccustomed to its action that a very small dose produces excellent effects, puts a little energy, even a little "devilment" into the poor creatures, who, during convalescence realize that destiny insists upon their surviving. Chinese and Japanese are much better patients, for they have faith, moral courage, they want to recover, and the natural constitution is more robust.

Racial idiosyncrasies are also of interest. Africans are much less subject to dengue than others and have it lightly, yet small-pox plays sad havoc with the negro and with the Arab of the Nile region. The Aryan races of Central Asia also suffer terribly from this disease, to the extent of complete depopulation in particular valleys and islands. Measles is the cause of great devastation among insular races, especially in warm countries. It assumes, among a people incapable of resisting a panic-creating disease, a more virulent type than is known in Europe. Ethiopians stand malaria pretty well, without after effects, as a rule. Pure-blooded negroes do not have yellow fever, nor do Hindoo coolies, and the Chinese are almost exempt. African races incur greatest danger from cholera, dying off with the greatest rapidity and no effort at resistance. There is scarcely time for any treatment. Europeans in oriental countries and the Hindoos suffer similarly. Bronchial catarrh, pneumonia, and consumption are particularly fatal among native dark races in Africa and Asia. Typhoid fever off the coast of Malabar is extremely dangerous to Europeans, though the natives escape with only mild attacks. Visitors to St. Kilda or the Society Islands will start from some slight cold an epidemic of influenza among the natives. Even a cold introduced by a passing vessel runs through Ascension Island as a severe epidemic, necessitating rest in bed and active treatment for days. Recent arrivals are lightly attacked, older sojourners more severely, and the natives often dangerously. In the island of Tristan d'Acunha the effect is more virulent, leading even to fatal results. Isolation from other races—due to situation, feuds, scant means of locomotion, and to religion—has accentuated, through heredity, liability to certain forms of disease and induced distinct racial idiosyncrasy.

The perpetual superiority of native inhabitants of the temperate-zone is owing to the formative conditions there, which develop the strongest constitutions. This temperate-zone superiority becomes at last a racial peculiarity that time cannot change. Brain and brawn of such calibre have really nothing to fear. And it is not too visionary to expect for them, on purely anatomical grounds, the conquest and control of the whole world.

THE DOCTOR IN MODERN SOCIETY.

THE physician of to-day exercises more or less influence upon all the affairs of life. In a sense he is the supreme educator, for juries refuse to convict; philosophers pause before considering abnormities of will, memory, or personality; the historian waits in his description of prophet and sibyl until the medical man has spoken. It is impossible to build a house properly, bring up children aright, discipline an army, or live with structure healthily developed and function of every kind unimpeded—which is the nearest approach to happiness for anyone—without first consulting the hygienist.

The modern doctor is everywhere—in society, in politics, mixed up with fine arts, religion, and philosophy. In a little paper written for *Médecine Moderne*, Maurice de Fleury thinks the medical man has just cause to be proud of his present position. Alphonse Daudet calls him the

last priest and supreme belief. Painters and sculptors owe much to medical science. Anatomy, for instance, is the basis of their calling. The debt of novelists is even greater. The naturalist school works on quasi scientific lines, and adopts methods common to all investigators of facts. The representatives of literature owe as much to Claude Bernard as to Balzac. This century is one of science, and among *savants* medicine occupies the first rank, because it is of wider scope and more human than any other branch. In his "Philosophical Dialogues," Ernest Rénan forecasts a social state of great splendor, in which the *savant* is king. Be the realization of this as it may, it is a significant fact that the practical needs of humanity are best known to the physician, who, in spite of himself, thus becomes a functionary of high order, invested in great degree with the welfare and happiness of the human race.

THE CONGRESS AND THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

The American Association of Obstetricians and Gynecologists has a grievance in which there seems to be a measure of justice. When the Congress of American Physicians and Surgeons was first organized, the American Gynecological Association declined to join the confederation. The promoters of the Congress naturally desired a representation of the important subjects of obstetrics and gynecology. We are told by Dr. Adam H. Wright, in his presidential address: "After a conference, some strong friends of the Congress decided to organize a new society of obstetricians and gynecologists. A preliminary meeting of a number of prominent obstetricians and gynecologists was held in Buffalo, April 19, 1888, with that object in view, and the result was that the American Association of Obstetricians and Gynecologists was organized, not in opposition to any other society in any sense, but largely in the interest of the new Congress."

A formal application for membership in the Congress was now made. But meanwhile the American Gynecological Association had changed its mind, and also applied for admission. It was admitted, while the new Association received notice that the following resolution had been passed by the executive committee of the Congress:

"*Resolved*, That it is the sense of this Executive Committee that they will not consider the application of any society which has not held at least two annual meetings."

The Association has now held three annual meetings and published its volumes of Transactions; yet it is still informed that it cannot become a member of the Congress.

We cannot pretend to discuss the merits of the question which the new Association raises more than to say that it appears on the face of it to have been treated unjustly. On the other hand, it would be difficult for the Congress to have two associations of gynecologists in its ranks. There ought in fact to be no need of two national gynecological associations, and perhaps the wisest and most generous course would be for those now existing to unite.

ANOTHER VIEW OF CHLOR-ANÆMIA.

Before a recent meeting of the Société Médical des Hopitaux, Dr. Hayem presented some excellent ideas in regard to chlor anæmia, based upon the careful study of seventy-two cases. This view displaces in part the old theory of its neurotic origin, though this might explain both the dyspepsia that is present and abnormities of the blood. The disease is primarily a condition of altered gastric chemistry, according to Dr. Hayem, which in time changes the character of the blood and induces other familiar phenomena. Upon this basis traditional therapeutics must undergo a sea-change and routine treatment take a back seat. Possibly the more modern notion of chlor-anæmia may explain the reason why the classic ton of iron fails to cure and quinine is of no avail. Of a surety, drugs in a stomach incapable of digesting them miss a brilliant destiny and become one more cause of disturbance. Upon Dr. Hayem's hypothesis, iron, arsenic, and quinine are interdicted always in the beginning of treatment. The most frequent gastric change in chlorosis is hyperpepsia. This and improper gorging with the usual drugs the learned doctor looks upon as a too frequent cause of gastric ulcer in women. When young men—also subject to the condition known as chlor-anæmia—present themselves for treatment of digestive disturbances, they are looked upon as dyspeptics or neurasthenics and thus escape the irritating effects of iron.

The dyspepsias of adolescence are as frequent in boys as in girls, and simply furnish a soil favorable to the development of chlorosis. When this disease declares itself, the dyspepsia already present is increased in severity and presents a serious obstacle to the cure of altered blood and circulatory function, especially if treatment is ill-advised and traditional. The best results are obtained by looking upon the entire abnormity as a gastro-intestinal disturbance of grave and rebellious character, and instituting a mode of treatment that includes rest, diet suited to individual peculiarity, digestive ferments, and such remedies as are capable, under the circumstances, of producing a tonic effect. These ideas are so thoroughly medical and reasonable that from the practical point of view they would seem to signalize real progress in the study and treatment of a disorder hitherto somewhat discouraging to patient and practitioner alike.

THE ABUSES OF "LOW DISPENSARIES" AND MEDICAL BENEFIT SOCIETIES.

A London weekly paper has recently published a long anonymous article by a medical man, purporting to disclose a stupendous system of fraud in medical clubs and dispensaries, including medical associations, mutual benefit societies, and medical benefits attached to insurance offices.

The author asserts that he is a physician of thirty years' work, who is "now making ten shillings a week, and living in one room containing a bed, a washstand, and two chairs." The abuses, we take it, refer to the enormous amount of medical charity, and to the pitiful sums which are paid for medical services by benefit societies. Serious charges are made against medical men also. The *Lancet*, commenting upon the article, admits that there may be

some truth in it, but deprecates the anonymous way in which it is presented.

We have at various times referred to similar evils which are growing rapidly in the larger cities of this country. Their existence is generally admitted, and we presume it will not be long before some sensational journal prepares a similar article for the delectation of its readers.

The question of the remedy is the perplexing thing. In the matter of benefit societies it seems as if only a wider education and knowledge would be needed to show what an error it is, morally and economically, to engage medical services on such a plan that a physician is compelled to treat hundreds of patients for a few cents per head, giving to each only a most cursory examination and a stock prescription.

As for the dispensaries, there is developing a feeling, among the managers of the better class, that there should be discrimination in giving relief, and that their proudest annual boast should not be that they have treated so many thousands, but that a goodly number of deserving poor have been treated well.

ARSENIC POISONING AND WALL PAPERS.

In his anniversary discourse before the New York Academy of Medicine, Professor Chandler performed a decided service to the medical profession by presenting the subject of arsenical poisoning from the sceptic's standpoint. There is no doubt that the majority of medical men, even outside of Boston, believe that chronic arsenical poisoning occurs from wall-papers, clothes, furniture, and various articles in the domestic environment. The dangers from these sources are generally admitted and described in systematic works, sanitary authorities have waxed eloquent over them, and legal restrictions have been established to prevent or lessen the possible harm.

Now, Professor Chandler thoroughly disbelieves in the reality of the dangers aforesaid. His line of argument is in the main rather negative than positive; that is to say, he throws the burden of proof upon the believers in the arsenical theory.

In this he is perfectly right, for the reason that chemical and physical facts make it *a priori* improbable that wall-paper or fabrics can be a source of poisoning. For arsenic is not volatile, and when fixed in paper or cloth can only be given off as a fine dust. In wall-papers, as made to-day and for the last twenty years, the surface is as a rule firm and glazed, and it is impossible to suppose that it can continually give off minute particles of its substance. But even supposing that wall-paper or clothes did do this a little, the amount is infinitesimal, and there is no clinical evidence to show that infinitesimal amounts of arsenic taken for a long time can poison a person. In factories where arsenious compounds are made, and in those where wall-papers are manufactured, arsenical poisoning is practically unknown.

The frequency with which arsenic is found in the urine is due simply to the enormous prevalence of this substance as an impurity in foods, medicines, waters, coal, and articles of domestic use.

The conditions which would demonstrate to a certainty that a person is poisoned with, we will say, arsenical wall-paper, have not yet been absolutely secured, and we doubt if they ever can be on human beings. If the matter were subjected to laboratory study, perhaps some absolute evidences of the arsenical idea might be produced. Let us hear of observations in which healthy animals, having been kept for a time in an unpapered room, get ill when the walls are papered with a modern moderately arsenicalized wall-paper. Let it be shown that there is arsenical dust or gas in the air, and arsenic in the tissues of the animal not due to arsenic in its food. Then we can believe in wall-paper poisoning.

THE HOUR TO EAT THE WATER MELON.

The *Medical Mirror* gives us the pleasing information that the best hour to eat water-melon is eleven o'clock A.M., or between three and four in the afternoon, or late at night. We presume that the *Mirror* will agree further that the best season of the year is summer, with humidity low and temperature high. When these conditions, thus scientifically established, are harmoniously concatenated the melon is harmless, and there is fun in St. Louis.

THE PRACTITIONER, THE CONSULTANT, AND MEDICAL CHARITY.

We have received the following letter from a prominent consultant in this city:

"Dear Sir: In connection with the subject of the abuse of medical charity, will you not allow me to say a word which is, in a measure at least, for the other side. For a good many years I have lectured and conducted a free clinic in this city. I have probably treated some patients there who could afford to pay a doctor, though I do not ever mean to do so. But let me add that for one case of this kind there are twenty in which the struggling young doctor has treated the patient until the money was gone; then, and not till then, he has sent him to a free clinic with a polite request for diagnosis and treatment. Another practice, which is more reprehensible, is this: A physician in the country gets a patient to pay his expenses to the city; he then takes this patient to a free clinic and secures advice gratis. I have known of many instances in which the physician had a long and expensive trip paid for on the ground, chiefly, that he knows the professor and can fix things so that the consultation will be free. Another variation on this interesting practice is to arrange so that the consultant's fee is, in some fashion or other, reduced, while the accompanying physician gets half.

"I would not like to convey the impression that such practices as these are the rule, for such is by no means the case. The majority of physicians, rural and urban, secure advice because they honestly want it for the patient's and their own advantage. But the abuses of medical charity have been frequently and graphically described, and always rather to the disadvantage of the teacher and conductor of the clinic. I venture therefore to present a somewhat different phase of the matter in the columns of your influential journal.

"Very respectfully, etc."

We are always ready to hear both sides of a question, and the evil, not to say dishonest, practices hinted at by our correspondent, call for strong condemnation. We

are glad to believe, as is stated, that such practices are not very common; but their infrequency is not a satisfactory excuse. We believe that the medical profession is, on the whole, greatly underpaid considering the total amount of work it does; and the physician who attempts to lessen the rate or amount of fees honestly earned does a gross injustice to his profession.

THE CORONER SYSTEM AGAIN.

It is quite time for the medical profession of this State to try again to initiate some reform in our coroner system. And it is gratifying to find that such attempt has been made. In an able paper on this subject, read before the Section on Public Health of the Academy of Medicine by Dr. Stephen Smith, the evils of the present system were portrayed and a plan for something better was set forth.

The coroner system is a relic of the past, and should become as obsolete as it is ancient. Aside from its practical deficiencies, and the political corruption which has been associated with its history, it has, as Dr. Smith says, an inherent defect.

The coroner's duties require the exercise of two important functions—one as medical examiner, and the other as a judicial examiner. The two functions should properly be represented by two persons.

It should be the duty of the medical examiner to ascertain accurately the cause of each sudden death, and if a crime has been committed it becomes the duty of the judicial examiner to hunt up the perpetrator of the crime. An improvement on the existing system of coroner's inquests would be made if the duty and power of investigation were left with the Board of Health, which is the proper repository of all vital statistics. The chief of the Board of Health, of course, should be a thoroughly competent physician, and he should have competent aides, to be known as medical examiners.

If, after careful investigation into the cause of a sudden death, these medical examiners find traces of criminality, then the case should be handed over to the Police Justice. Every small town has a health board and a police magistrate, so that this system could apply all over the State, the local boards being subordinate to the State board. Experience had proved, said Dr. Smith, that the health physician is more competent than the average coroner in investigating cases of death. Frequently the coroner is a disgracefully ignorant and incompetent man. Coroners' juries should be abolished.

In the discussion on the subject after the reading of the paper, Dr. Philip Donlin defended the present system. His chief arguments were, that no change could be made without great expense, that the present coroners now had as aides "medical men who were held in high esteem by most eminent physicians," and that they did a great deal of work. He admitted that there ought to be more coroner's physicians and better facilities for doing work.

Despite all that was or could be said, however, we

[illegible] PRICE, and STONE related experience bearing more or less on the medico-legal aspect of the case, especially as concerned reflex pains from pelvic disease resembling joint disease.

Medico-Legal Aspect of Intestinal Surgery.—Dr. J. D. S. Davis, of Birmingham, read a paper with this title. To escape an action at law in the class of cases under

News of the Week.

The Medical Library of the Late Dr. Fordyce Barker is now in the possession of the New York Academy of Medicine. It embraces some rare and interesting works. Portfolios of exceedingly valuable plates, lithographed and in crayons, on gynecological subjects form an interesting part of the library, which is unusually rich in full sets of serial publications, many of which have been out of print for a number of years. There are about six hundred monographs and pamphlets on medical subjects, most of which bear the autograph signatures of the authors, and cover not only the entire field of medicine and surgery, but also science in all its branches. Among the rare works long since out of print the following are the most precious: "Childbirth," James Gillemeau, London, 1612; "Birth of Mankind," London, 1634; "L'Idée et le Triomphe de la Vraie Médecine," M. Callot, Paris, 1742; "Essay on Improvement of Midwifery," London, 1733; "La Manière de Nourrir les Enfants à la Mammelle," Scevale de Sainte Marthe, Paris, 1698; "Manual of Practical Midwifery," James Reid, London, 1836.

Another Midwifery Dispensary.—Mrs. C. P. Huntington has given $2,000 to defray the expenses of a lying-in department of the New York Post-Graduate Medical School and Hospital. In this department poor women will be attended at their homes free of charge.

Dr. Nathaniel C. Husted, who for the last thirty years has practised medicine in this city, died at his home in Tarrytown, on November 20th, in the sixty-sixth year of his age. Dr. Husted was born in 1825 at Greenwich, Conn. He came to this city, and entering the Medical College of the University of the City of New York, was graduated from it in 1853. At the outbreak of the civil war he entered the army as surgeon, and was deputed by the Governor of New York to attend to the wounded at Fortress Monroe and the Army of the Potomac. He was also at one time surgeon to the Police Department and to St. Luke's Dispensary. In 1878 he removed to Tarrytown on account of his health, but, nevertheless, did not entirely give up his extensive practice in this city.

Suicide of a Medical Student.—A young man from Texas, who had been studying medicine at the University of Pennsylvania, became insane and was taken to a hospital, where he committed suicide by cutting his throat with a piece of glass.

Examinations by the Medical Board of New York.—The Attorney-General of New York has given a ruling of some importance to foreign graduates. He interprets the law to require that all physicians having foreign diplomas only, and desiring to practise in the State, must undergo an examination by the State Medical Board before a license can be issued.—*New York Medical Journal.*

The Barge Office Physicians.—When the Federal Government assumed charge of immigration at this port a corps of young surgeons from the Marine Hospital Service was detailed to examine and care for sick immigrants. The provisions of the new law made a rigid physical examination of immigrants necessary to determine whether they should or should not be landed. More

doctors were needed than when the old State Board's single medical examiner passed on the throngs that came through Castle Garden. Then consumptives were not in the prohibited class. Now, even if an immigrant has incipient tuberculosis he is sent back. There are five men in the medical department of the Barge Office. They are no longer connected with the Marine Hospital service, but belong to a recently organized service of their own.

Washington and Its Diarrhœa.—Dr. Weir Mitchell sends the following note to *The Medical News*: "I consider Washington to be so clearly the best place for our Congress that I am moved to say a word as to the cause of the diarrhœa from which I, in common with many others, suffered during our second and very successful meeting. The water was not to blame. I drank no drop of it, except as it was used boiled in coffee. I know of others who suffered despite this and every other precaution; also, the manifestation was too general to have been due to food, for it affected people living in hotels and in private houses. Finally, it existed over a large part of the country—in Newport, R. I., for instance, whither I went after a week in the Maryland hills, where also it was sharply felt. The cause, therefore, was not the product of Washington, nor should it be allowed to influence us when again we come to summon, for a like purpose, the remarkable body of men which constituted the Congress." We have heard of other gentlemen who did not drink water while in Washington and yet had the diarrhœa. The epidemic theory, however, is weakened by the fact that most members did not have the diarrhœa before going to Washington or after leaving it.

United States Medical Practitioners' Protective Alliance.—The report of the proceedings of the first annual meeting of the United States Medical Practitioners' Protective Alliance, held at Baltimore, June 11, 1891, just published, contains the Constitution and By-laws, and the addresses of the Founder, Dr. J. H. DeWolf, of the President, Dr. W. H. Crim, and of Dr. W. V. Wilson. The objects of the Association, as stated by the Constitution, are "to maintain organized co-operation among the practising physicians who are legally qualified to practise in their respective States and in good standing in the profession, for the purpose of protecting medical practitioners from the abuse of dispensaries, that treat many who are well able to pay; from the unjust competition caused by short-term, quick graduating, and inferior medical colleges; to endeavor to promote the passage of just and equitable laws regulating the practice of medicine in all the States, so that the license to practise issued by any one State shall be valid in any other State; and to devise means to enhance our financial condition (and thereby our usefulness) in every honorable way, and to derive the incalculable benefits that only can be obtained by combination and unity of action."

Music and Medicine.—It seems to be thought by some persons that the use of music for medical purposes has never been seriously attempted. But as a matter of fact the subject has quite a large literature of its own, as may be seen by referring to an interesting article on "Medical Music" in the "Curiosities of Literature," by the elder Disraeli. A glance at this will show how many and painstaking have been the efforts made by succeeding generations of musicians and medical men to apply the strains of music to the relief of human suffering. Somehow the various revivals never had a long survival.—*Medical Press.*

Modern Medicine.—The first volume of a French work on "Modern Medicine" has just made its appearance. Professors Charcot, Bouchard, and Brissaud are the editors. The work will be completed in six volumes, within two years.

A Daily Medical Journal has been started in Philadelphia.

A Beneficent Quarrel.—Pittsburg is at present infested with quacks, and they are bidding for patronage by the destructive though laudable device of traducing each other. The newspapers are full of "exposures," "challenges," and other paper bullets calculated to pulverize the opposition. An occasion where telling the truth will best serve their purpose is so rare to these gentry that they evidently enjoy the novelty, and intend to indulge it to the utmost. As a result, the newspapers are enriched, the public is informed, and everybody is amused. By the time the merry war is over, such shreds of reputation as they may originally have had will be completely destroyed, and gentle peace will return to brood over a much benefited community.—*Pittsburg Medical Review.*

Nurses Recruited from the Criminal Classes.—Dr. Leonard Weber, of this city, writes under date of November 24th: "Again a brutal outrage has been committed by a male nurse, and on this occasion upon the wife of the unfortunate patient whom the man was engaged to attend. In May last two invalids were robbed by professional (?) nurses. The question was asked then, how a convicted murderer came to be a professional nurse, and on whose responsibility a robber and brute was introduced into the chamber of a sick man, lying ill at a hotel, and evidently without family or friends about him. Now, such dreadful recurrences ought to be prevented, and if there is not an organization among the physicians of this city to guarantee the exclusion of criminal persons from the list of professional nurses, it is high time that we have one. I believe it ought to be the business of the New York County Medical Society to establish a bureau for the registration of male nurses, and the committee appointed for the purpose should carefully examine the credentials of an applicant for registration, and no person be granted the use of the registry unless these are satisfactory. The nurse may be charged a small fee for registration, and if convicted of grave errors in conduct or work, should at once be dropped from the list. Physicians and druggists should be supplied with revised lists on application or otherwise. Some of our private nurse agencies are fairly reliable, but none of them have the time and means to investigate the record of their nurses."

the columns of your influential journal.

"Very respectfully, etc."

We are always ready to hear both sides of a question, and the evil, not to say dishonest, practices hinted at by our correspondent, call for strong condemnation. We

Society Reports.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Fourth Annual Meeting, held at Richmond, Va., November 10, 11, *and* 12, 1891.

(Continued from page 641.)

LEWIS S. MCMURTRY, M.D., OF LOUISVILLE, PRESIDENT

SECOND DAY, WEDNESDAY, NOVEMBER 11TH.

DR. MOORE, of Richmond, made some remarks, welcoming the members of the Association to the city.

Medico-Legal Aspect of Pelvic Inflammation.—DR. W. W. POTTER, of Buffalo, read the paper. He began by saying that pelvic inflammations in women had been discussed from almost every point of view excepting the one he had chosen. He based his paper on a case whose history may be epitomized as follows:

A young married woman, pregnant, fell into a shallow street excavation, was immediately helped out, and walked home. In about a fortnight she suffered pain and called a physician, who diagnosticated it general peritonitis. She had several recurrent attacks prior to her delivery, which occurred about three months after the alleged fall, when she was delivered by forceps of a still-born child. A few weeks after confinement she was seized with pain in the right hip-joint, which was finally diagnosticated and treated as coxitis. The right extremity was placed in an extension splint, where it was kept for a period of two or three months. A suit for damages was entered against the city and paving contractors, and several experts were invited by the counsel on both sides to examine the patient. On one side of the prosecution it was held that the woman's sufferings were due entirely to the alleged fall, while the defence held that her condition was due to circumstances entirely independent of any injury; that she had suffered from recurrent pelvic inflammation; that there was no hip-joint disease and never had been, and that she was not entitled to damages on that ground. A verdict was given for a nominal sum. A per appeal was taken. The author called attention to the fact that reflexes pertaining to a disease of the pelvic organs were very common, and especially were they prone to manifest themselves in the larger joints of the extremity, notably the hip and knee. This might reasonably be expected when the intimate nerve-communication between the pelvic organs and hip-joints were recalled. These reflexes had often been treated instead of the disease itself, and had been called neuralgia, rheumatism, and various other names. The author cited a paper by Dr. R. H. Sayre, in which he referred to the fact that many such cases had been treated for genuine Pott's disease with corsets and braces, that were ascertained to be due to disease of the pelvic organs with spinal reflexes simulating Pott's disease. He emphasized the points of his paper as follows:

1. The intimate anatomical relations between the pelvic organs and the larger joints, especially the hip- and knee-joints, render them liable to reflexes. 2. The importance of careful diagnosis at the outset, lest grave errors, and possible disastrous consequences, may result from misdirected treatment. 3. The medico-legal bearing that errors of judgment in diagnosis and treatment may have in relation to the patient, as well as upon the reputation of the physician.

DRS. READ, of Cincinnati, ENGELMAN, of St. Louis, HOWARD A. KELLY, of Westmoreland, OPIE, PRICE, and STONE related experience bearing more or less on the medico-legal aspect of the case, especially as concerned reflex pains from pelvic disease resembling joint disease.

Medico-Legal Aspect of Intestinal Surgery.—DR. J. D. S. DAVIS, of Birmingham, read a paper with this title. To escape an action at law in the class of cases under consideration, the surgeon should have a knowledge of the operation to be performed; should recognize the necessity for an operation; exercise at least ordinary skill in its performance. To assume ability to give expert testimony, one should at least have had experience in intestinal surgery on the lower animals. Certainly, one should not attempt an operation on the human subject without first operating on dogs and the cadaver, and the percentage of recoveries from operations on animals should have been raised to not lower than fifty. There was no adequate legal protection for the physician or surgeon against unjust civil or criminal prosecution.

DR. ROSS, of Toronto, Canada, referred to a case of gastro-enterostomy in which, as an assistant at the operation, he profited greatly by experiments which he had made on dogs and the cadaver; and like others who discussed the paper, he expressed the opinion that one should not undertake intestinal surgery without first having acquired some experience and skill in doing the operations on lower animals.

DRS. WESTMORELAND, DEAN, W. E. B. DAVIS, and PRICE, impressed the importance of operating as soon as possible, say within half an hour, after gunshot and stab wounds of the abdomen.

DR. MARCY suggested the use of gas after closing all visible perforations, in order that possible concealed ones might be revealed. He preferred oxygen gas.

DR. R. T. MORRIS thought some display of medico-legal knowledge on the part of the doctor would deter money-seeking attorneys from pushing a weak case so urgently in the lower courts, knowing that an appeal would be taken and the decision reversed by the better informed judge.

DR. W. E. B. DAVIS said he had great admiration for Dr. Senn, but he was convinced that his gas-test had been over-estimated in value; yet whenever in court a surgeon replied to the interrogatory of the prosecuting attorney, that he had not in the given case resorted to this test, it damaged his cause.

DR. BAXTER referred to a case seen by him in consultation on the sixth day, in which the man had seventeen balls enter the abdomen, yet after a few months he re-

expected in a woman whose system had been [illegible]. The treatment was expectant, and astringent applications were made within the uterus. At the next visit the tumor would absolutely disappear and return again, but there was nothing like a contraction of the pregnant uterus. In time this tumor could not be felt at all. The patient then remained away for some time, and then the parts of the child could be made out, by palpation through the vagina, with very great distinctness. The parts of the child could now also be made out by palpation over the abdomen. It seemed almost impossible that the uterine wall could intervene. Supposing there was extra-uterine pregnancy, the patient was instructed to give notice in case symptoms of rupture, etc., should develop. The applicator gradually went in further, but never in an anterior

more, said his observations on this subject were based on laboratory studies. Suppuration, he said, was caused by micro-organisms, most commonly by the staphylococcus pyogenes albus, and aureus. Prevent invasion of these germs, and you prevent suppuration. Disinfection meant the destruction or actual removal of such germs. By the use of the Arnold steam sterilizer the surgeon's armamentarium could be absolutely sterilized. But two more avenues of possible infection remained, namely, the hands of the surgeon and the patient's own body. Infection by the latter means might be called auto inoculation. He presented his observations and conclusions regarding the former only. On placing some of the scrapings of the epidermis from the fingers in the test-tubes, numbers of the staphylococcus pyogenes albus and some of aureus would develop. Wash and scrub the hands with the brush, soap, and water five to twenty minutes, and the scrapings would still develop the micro-organisms in the test-tube, though in smaller numbers. Bichloride of mercury, 1 to 100 and

1 to 500, used on the hands, also failed to destroy the germs, although it inhibited their further growth until the salt was removed. Other agents much in use in cleansing the hands, including peroxide of hydrogen, also failed to destroy the germs, as shown by similar tests. No other means had been as efficient as permanganate of potash applied to the hands in saturated solution, and then decolorized by a saturated solution of oxalic acid. If, however, but a single measure were to be made use of, he would recommend thorough scrubbing with soap and water, because, in a mechanical way, it so far cleansed the hands of germs that what few remained might not become dislodged during the operation and contaminate the wound. Where accessible, one should also use the permanganate solution followed by the decolorizing oxalic acid.

Dr. Ross, of Toronto, thought men working in laboratories and bacteriologists were a little confusing. The germicide recommended yesterday was condemned to-day, and who knew but what that recommended to-day would be condemned to-morrow? He felt that bichloride had done him a good service, and he was not prepared to suddenly discard it entirely because the experiments carried on in laboratories seemed to point to its inefficiency. It was not quite clear just to what the success of our operations was due in many cases. He had during the past summer obtained better results in his operations in the hospital, under ordinary aseptic precautions, than formerly, when the walls were carefully washed down with bichloride, etc.

Drs. Buckmaster, Marcy, Wyeth, Davis, and Engelman thought Dr. Kelly in this work was moving in the right direction.

The Pedicle in Hysterectomy; How Formed; Its Subsequent Behavior; Its Final Condition.—Dr. I. S. Stone, of Washington, read a paper with this title, describing the different methods of disposing of the pedicle, and showing up the advantages of the internal method, although admitting the remarkable success obtained by some, especially Dr. Joseph Price, with fixing the pedicle in the abdominal wound.

Dr. Ross practised a modification of Eastman's method.

The annual meeting of the United States Medical Practitioners' Protective Alliance, held at Baltimore, June 11, 1891, just published, contains the Constitution and By-laws, and the addresses of the Founder, Dr. J. H. DeWolf, of the President, Dr. W. H. Crim, and of Dr. W. V. Wilson. The objects of the Association, as stated by the Constitution, are "to maintain organized co-operation among the practising physicians who are legally qualified to practise in their respective States and in good standing in the profession, for the purpose of protecting medical practitioners from the abuse of dispensaries, that treat many who are well able to pay; from the unjust

Murtry having thanked the Association for the honor of electing him its president, and referred in general terms to the position of the South in the country's history, proceeded to make

A Plea for Progressive Surgery.—The term conservative had come to be used in a different sense in surgery from that of "having power to preserve in a safe or entire state, or from loss, waste, or injury," as Webster had defined it. It had been made of late to have a very wide and altogether arbitrary significance, being often used in antithesis of progressive surgery.

Not many years had elapsed since it was the custom of surgeons to defer operative interference in cases of ovarian cysts until the patient had been reduced by emaciation, and this was pronounced conservative. At present, to operate in such cases as soon as the tumor was discovered was very properly regarded as the conservative course. In some other conditions a course was pursued to-day whereby operations were deferred until the patient was in a dying condition, and, sad to say, it was called conservatism. All knew that throughout the land, every year, many women perished of suppurative conditions in the pelvis for want of operative treatment; yet, under a plea of conservatism, we heard the great advance which had been made in pelvic surgery, whereby so many lives had been saved, denounced from the rostrum and ridiculed in the medical press. That some rash enthusiasts, or that some injudicious operators, should misapply an operation of great worth was not new, but it did not justify inveighing against the operative treatment of such a grave form of disease without discrimination.

Surgery was advanced more by the aggressiveness of the surgeon than by timidity.

Injuries to the Pelvic Floor, and the Method of Repairing Them.—Dr. Thomas Addis Emmet, of New York, read an exhaustive paper expressive of his views of the structure of the pelvic floor, of what occurs when injured during labor, and of how to effect its repair. The following points, taken here and there from the paper, may convey some idea of the author's views. The grooves or sulci formed by the flattened walls of the vagina, were simply the result of lifting the posterior wall up to the anterior wall, while at the same time the needful degree of lateral traction was exerted by the fascia. The fascia here, as a continuation of that in the pelvis, held the muscular mass in a common sheath. The proper circulation of the blood through the pelvis could be maintained only so long as the integrity of the connective tissue or fascia was preserved. As the veins ran in and out of the fascia they received from the fascia and elastic surrounding tissue that degree of support needed to prevent undue dilatation and straightening from a normally tortuous course. He did not accept the teaching of obstetricians, that during the progress of labor the pelvic fascia and muscles softened down to permit of passage of the child's head. The increase in the transverse diameter was rather to be accounted for by shortening or decrease in the length of the canal. The uterus would be observed to be nearer the vaginal outlet at the close of labor than at any other stage. The author likened the passage of the child through the vaginal canal to the advance of a piston through a cylinder to which a tapering nozzle was attached. In the case of labor the head reached the narrower portion of the canal where the vagina entered the muscular diaphragm at the floor. If the vagina did not shorten sufficiently, and the force continued, a rent must take place in the long axis of the vagina. If the tear stopped short of the fascia or posterior commissure, not entering the rectum, probably no serious results would follow after the parts had cicatrized.

When the sphincter was torn the head escaped into the rectum, was delivered through the rent in the muscle, as was proven by the fact that the fascia sometimes was not torn. No greater evil consequence followed such an injury through the sphincter than incontinence. But the common injury present in women said to have rupture of the perineum, was a transverse one to the vagina, a rupture of the fascia where it came down and was reflected over the muscles. Sometimes no scar whatever could be detected to indicate the existence of a most marked degree of injury. In these cases at least it could be proved that there certainly was no perineal body, for the two fingers, one inside and the other outside, could be brought almost in contact with each other, only skin and vaginal mucous membrane intervening. The vaginal outlet thus became like the mouth of a bag from which the puckering string had been withdrawn, yet no injury was visible.

The author explained the consequence of neglected tears, the action and result of separation of the perineal muscles, his method of operating, etc. In accord with his view of the pathology of the injury, he had gradually perfected an operation, whose purpose was to catch up the retracted fascia at a point, and in such a manner, that he could take in the slack of the fascia throughout the pelvis. By this procedure the posterior wall of the vagina

was lifted up and drawn forward in contact with the vesico-vaginal septum, the separated levator ani muscles were apparently brought together, the concave outline of the recto-vaginal septum was restored, the blood-vessels were supported, the circulation again became normal, coitus became pleasurable instead of painful and repulsive. The operation was described in detail. It was not, the speaker said, a new operation, differing from the one he had for years performed only in the manner of putting in the sutures. Now, these were all within the vagina, formerly a part of them were in the vulva.

Drs. Joseph Price, Howard Kelly, and Buckmaster made use of Emmet's later operation with slight modifications.

Dr. Marcy also made some remarks on the procedure practised by him.

The Growth of Fibroid Tumors of the Uterus after the Menopause.—Dr. Joseph Taber Johnson, of Washington, read the paper. It had fallen to his lot, the past five years, to see as many as a dozen cases of growing fibroids of the uterus in women over fifty or sixty years of age, women who had been told by physicians that probably after the menopause the tumor would decrease in size or disappear. He did not think that with our present knowledge of the progress of fibroids, and skill with which operative treatment could be carried out, advice to wait for the menopause was wise; at any rate, the patient could be given no positive assurance that the tumor would diminish or cease to grow after the menopause, and it might become cystic or enlarge, and cause grave symptoms, and make a later operation more dangerous.

Dr. Kollock said that in his experience where fibroids continued to enlarge at the period of the menopause they were cystic.

Dr. Joseph Price did not hesitate to urge the removal of the uterine appendages in all cases of small fibroids, and in others to remove them. Rapid growth of the tumor after the menopause was not uncommon. Cystic or malignant change would be avoided by an operation.

Drs. Stone and Engelman agreed with the author.

The Surgical Treatment of Anterior Displacement of the Uterus.—Dr. A. L. Reed, of Cincinnati, in a paper on this subject, took the view that anterior displacements existing in pathological degree were proper for gynecic art. Of course, where known, the cause should if possible also be removed. This might call for massage and other treatment not strictly surgical. The operation which he performed was a modification of Dudley's, of Chicago. Relief had been given so far as dysmenorrhœa was concerned, but his sterile patients had not yet conceived.

The Part the Shoulders Play in Producing Laceration of the Perineum, with Suggestions for Its Prevention.—Dr. W. D. Haggard, of Nashville, in this paper first showed that authors had not fully recognized the part played by the passage of the shoulders in the production of laceration of the perineum, and for this reason conflicting opinions prevailed regarding the proper position of the woman, and management of the case at this stage. The diameter of the shoulders was greater than that of the head, the shape placed the perineum at a greater disadvantage, this structure contracted around the neck on the passage of the head, it often had not time to relax before a forcible contraction of the uterus took place, and if the woman were on the back these disadvantages would be enhanced. Slow delivery at this stage was desirable, yet Lusk had advised pressure upon the uterus in order to aid its expulsive effort.

In addition to placing the woman in the left lateral position, forcible expulsion, with its attendant dangers during the passage of the head and body through the perineum, should be avoided by supporting, not the perineum, but the advancing part. This was accomplished with the thumb in the rectum and the fingers on the perineum or in the vagina. Supporting the perineum would do harm rather than good.

Third Day, Thursday, November 12th.

Abdominal Section in a Case of Cyst of the Mesentery.—Dr. J. A. Goggans, of Alexander City, Ala., showed in the first part of his paper the rarity of tumors of the mesentery, only a few cases of cyst and lipoma having been removed, and usually, in them, with a fatal result. In his own case, which occurred in a young lady, the abdomen began to increase in size in 1890, and she was treated by several physicians for abdominal dropsy. He saw her in February, 1891, and used the aspirator, drawing off a quart of dark-colored fluid for diagnostic purposes. Dr. W. E. B. Davis consented to assist at the operation, which was done February 24th, when on making a long incision in the median line he came down upon a tumor which was found to be within the fold of the mesentery. Enucleation had to be abandoned because of severe hemorrhage, and the tumor was drawn into the abdominal opening, emptied, and a glass drainage-tube introduced. Hot-water injections were made into the tube frequently, until after some days it was withdrawn and a smaller tube introduced. The patient made a good recovery.

Dr. R. T. Morris mentioned the need for care, in abdominal operations in general, not to make an opening into the mesentery, as through this opening, although small, hernia was likely to take place.

Thinness of Uterine Walls Simulating Extra-uterine Pregnancy.—Dr. G. J. Engelman, of St. Louis, related two cases in illustration of his subject. The first patient had had three children in rapid succession, was nursing the last one, aged twenty months, had not menstruated, was weak. She came to the clinic complaining of something coming down, and of a swelling and pain in the right groin. The tumor in the groin was movable, the soft copper applicator entered the uterus over three inches in a slightly anterior direction; no connection could be made out between the uterus and tumor, the latter seemed superimposed upon the former, or was possibly in the anterior wall. It was apparently a solid, round, hard tumor, in no way resembling the pregnant uterus. The condition of the uterus was such as might be expected in a woman whose system had been drained. The treatment was expectant, and astringent applications were made within the uterus. At the next visit the tumor would absolutely disappear and return again, but there was nothing like a contraction of the pregnant uterus. In time this tumor could not be felt at all. The patient then remained away for some time, and then the parts of the child could be made out, by palpation through the vagina, with very great distinctness. The parts of the child could now also be made out by palpation over the abdomen. It seemed almost impossible that the uterine wall could intervene. Supposing there was extra-uterine pregnancy, the patient was instructed to give notice in case symptoms of rupture, etc., should develop. The applicator gradually went in further, but never in an anterior direction in the region of the sac where the fœtus was found. The patient miscarried about the fifth month, showing that there had been uterine pregnancy. The other case was very similar.

Dr. Ross did not think thinness of the uterine wall should lead to a mistaken diagnosis of ectopic pregnancy. Where he found extreme thinness he doubted whether the pregnancy was extra-uterine, and waited for time to clear up doubt.

Dr. Rhoe, of Baltimore, thought rectal palpation would have revealed the true character of the cases related by Dr. Engelman. He and others doubted the diagnostic value of the sound, and spoke also of its dangers.

Removal of Carious Bone by Hydrochloric Acid and Pepsin.—Dr. Robert T. Morris, of New York, gave the results of experiments which he had made on the absorption of bone by muriatic acid and pepsin. It had been stated that the dilute acid would decalcify and cause

the diseased bone to disappear, and not attack the healthy bone. He found that a five per cent. solution of hydrochloric acid would decalcify diseased bone placed in the solution in six hours, but it also had the same effect in a live terrapin, but after a much longer period, or thirty hours. It was his belief that a two or three per cent. solution of the acid could be used safely in cases of necrotic or carious bone in man or child, but it was necessary to make alternate use of the acid and pepsin, the latter being used to digest the organic matter, and clear the bone for further action by the acid.

Drs. Brown and Goggan related cases in which dilute muriatic acid caused recovery from necrosis. Dr. Brown's case was one of necrosis of the toes with dry gangrene, and the acid used was the dilute officinal solution.

The Present Status of Cerebral Surgery.—Dr. Landon Carter Gray, of New York, read a paper on the modern aspect of cerebral surgery. He briefly reviewed our present knowledge of localization of functions of the brain. We were well acquainted with the functions of the motor area—of the third frontal convolution, the frontal lobe, the island of Reil, the two upper temporal convolutions, the cuneus, certain portions of the basal ganglia, the base of the brain, and the cerebellum. We knew nothing, or had still under discussion, the question of the localization of the centres for the sensations of touch, pain, muscular sense, temperature sense, most of the parietal lobe, and most of the temporo-sphenoidal lobe, with the exception of the olfactory lobe. Operations for fracture of the skull, with or without hemorrhage, for abscess, and for tumors that were removable and localizable, were usually successful; those for so-called idiopathic epilepsy were utterly valueless, as were also those for epilepsy supposed to be due to genital or ovarian irritations; while those done for epilepsy due to removable and localizable lesions of the intra-cranial contents were usually successful so far as the lesion was concerned, although it was a grave question as to whether the epileptic habit was ever cured; the latest operation for idiocy supposed to be due to premature ossification of the fontanelles was still under discussion and consideration, the cases being too few and too recent to permit of any conclusion, while the operations for hydrocephalus and for epilepsy due to such early infantile and fœtal lesions as porencephalus, hemorrhage, and meningitis were indefensible. He impressed upon surgeons the great difficulty that there often was in finding a subcortical lesion of the centrum ovale that was deep-seated or small; and the fact should be borne in mind that there might be no decussation of the motor fibres from the hemispheres, so that a lesion would be found upon the same side as the paralysis.

Dr. Hunter McGuire trephined a negro who had epilepsy and had degraded to a beast. He could give no account of his condition for years. There was very little depression of the external plate, greater depression of the internal. The man began to improve at once mentally, asked about war matters, his mind reverting back to what had taken place six years before, when, it was learned, he had sustained an injury of the head. The time between the accident and the operation was a blank. Occasional results like this lent some hope from an operation, but he had performed all sorts of operations for the relief of epilepsy, usually with no permanent result.

Some of the Complications of Psoas Abscess.—Dr. J. McFadden Gaston, of Atlanta, read the paper. These cases should not be confounded with abscess in the psoas region formed by burrowing of pus from vertebral disease. Scrofula and tuberculosis played no part in the etiology, unless incidentally. Two cases of inflammtion of the psoas with abscess had come under his observation, one of which he had already published. The second one resulted from the kick of a mule. It was still under observation, and he had reason to hope that the abscess would yet open externally, like in the first case, although there had already been escape of pus per anum, showing that the colon had been perforated. A practical lesson taught by the cases was that if we would avoid a perforation into the gut, the direction of least resistance, we should resort to incision over the region of the abscess as soon as there was evidence of pus, and encourage pointing externally. An exploratory needle might be used to discover pus, and finding it, make an external outlet at once.

Opossum-tail Suture.—Dr. H. O. Marcy, of Boston, who had long made use of the suture obtained from the tail of the kangaroo for ligature purposes, with excellent results, said he had recently had his attention called to the long and strong fibres present in the tail of the opossum, which he thought might answer ligature purposes much better than catgut. He showed an opossum with the tail dissected, nicely illustrating the length and strength of the fibrous tendons.

The speaker had often had opportunity to inspect vessels long after they had been ligated with kangaroo tendon, and found the tendon had not been absorbed or encapsulated, but had become a part of the living tissue. The importance of this observation need not be dwelt upon. He always buried his sutures, so that amputation and other wounds seldom needed further attention.

Venomous Serpents of the United States, and the Treatment of Wounds Inflicted by Them.—Dr. Paul B. Barringer, of the University of Virginia, presented his subject verbally and by illustration. The serpents of the States were classified as follows: the columbrine, which were harmless; the elopidæ, of which there was but a single poisonous species; crotaline, which included rattlesnakes (two genera), copperheads (two species), and the water-moccasin (one species). Of lizards there was one, the Gila monster, which he regarded as venomous only when in a rage. Its venomous sac he believed to be outside the lower jaw. In the rattlesnake of about four feet the sac would contain about fifteen minims of venomous fluid, in the copperhead the amount was less, but only a small part of this would kill a man if it were injected into his circulation. The venomous fluid contained, in different proportions according to the kind of snake, venom peptone and venom globulin. The former caused temporary depression of the heart and blood-pressure, then gradually produced paralysis of the spinal cord, extending upward, and causing death by asphyxia. Venom globulin had a similar paralyzing effect on the cord, but in less degree, its action being characterized especially by destroying the coagulability of the blood and causing marked swelling. In his experiments—proving, as he thought he did, that Weir Mitchell was in error when he claimed the venom contained bacteria—the author said he found, much to his own surprise, numerous hæmatoid worms in the fluid when pressed from the venom-sac through the snake's asepticized tooth.

Speaking of treatment, Dr. Barringer was sarcastic in his remarks upon the prevailing custom among the laity of filling the poor victim with whiskey. He believed this was the cause of more deaths than the bites of serpents. Strychnine, having an excitant action on the cord, might in large doses, one-thirtieth to one-twentieth of a grain, retard or prevent the paralyzing influence of the poison. The bite of a cowardly snake, one running away, was less dangerous than that of one which stood on the defensive. In this country they were seldom aggressive. Apply a tourniquet tightly and immediately; cut out the bite; suck it. Liquor potassi injected into the wound would render the poison innoxious. Permanganate of potash would also be effectual, applied early enough to the wound.

Imperforate Rectum.—Dr. George B. Johnson, of Richmond, treated of this subject in the way generally approved of in surgical works, and related two cases which had come under his observation. He showed his last patient, a child in which he was unable to reach the rectum by the perineal route, and therefore had made an opening into the colon in the inguinal region. This was

done last summer, and the child was fat and strong. There was some prolapsus, which he hoped to overcome later by making the opening smaller.

Induced Abortion for the Relief of Nausea and Vomiting.—Dr. Thompkins, of Richmond, gave in detail efforts to overcome the vomiting in a case of pregnancy, resort being had at last to induced abortion; but death took place some days later. This result was to be accounted for by the reduced state in which the patient was left by a previous injury to a lower extremity, and by the nausea and vomiting interfering with nutrition.

Election of Officers.—*President*, Dr. J. McFadden Gaston, of Atlanta, Ga.; *First Vice-President*, Dr. C. Kollock, of Cheraw, S. C.; *Second Vice-President*, Dr. George Benjamin Johnson, of Richmond, Va.; *Secretary*, Dr. W. E. B. Davis, of Birmingham, Ala.; *Treasurer*, Dr. H. P. Cochrane, of Birmingham, Ala.; *Member of the Council*, Dr. Hunter McGuire, of Richmond, Va.

Next meeting to be held at Louisville, Ky., the second Tuesday in November, 1892.

NEW YORK ACADEMY OF MEDICINE.

Anniversary Meeting, November 19, 1891.

A. L. Loomis, M.D., President, in the Chair.

The Academy's Prosperity.—The President, on taking the Chair, made a few remarks to the general public, which had been invited by card to attend the anniversary meeting, on the prosperity shown by the Academy the past year. The increase in membership had been greater than during any preceding year; larger additions had been made to the library, and a great deal of good scientific work had been done in the sections and general meetings. The Academy had grown more and more in the confidence of the public in all matters. The new building had more than fulfilled their expectations, and it was fast becoming the centre of all the medical activity of the city. He then introduced Professor Charles F. Chandler, who was to deliver the annual address.

Arsenic in Common Life.—Professor F. Chandler said that he had accepted the President's invitation to deliver the annual address with some hesitation, doubting whether he would be able to present any scientific subject in an interesting way to an audience composed of both physicians and the public. He said he had no paper to read; that his remarks upon "Arsenic in Common Life" would be based upon some notes which he had been able to make recently. In common with everyone else in the community, he had grown up to regard arsenic as a terribly poisonous substance. He found floating about in medical journals and public press various statements as to sickness produced by arsenic which existed in wall-paper, etc. When he became connected with the Health Department it occurred to him that it might be well to inquire into the subject of arsenical wall-paper, and if he should find any truth in the stories regarding its injurious effects upon the health of the community, it would be well to have laws enacted prohibiting its sale. In this state of mind he first consulted some of the medical profession. If he remembered correctly, the first physician to whom he mentioned the subject was the late Dr. John Dalton. His remark was, "Has that old humbug come around again?" That rather surprised him, and he consulted several other physicians, but did not succeed in finding one at that time who seemed to think there was anything in poisoning from arsenical wall-paper.

It then occurred to him to look over some of the articles setting forth the dangers of arsenic in wall-papers, etc., and he must say the evidence was not of a very satisfactory kind—not such as would be received in a court of law. He then looked up the evidence offered by some chemical authorities, and found on careful scrutiny that their conclusions were not warranted. He then did a little experimenting. He had large pieces of wall-paper, thickly coated with arsenic, hung where air passed over them which previously had passed through certain chemical solutions, with a view to decomposing the arsenic in the paper, and the air itself was rendered damp; but he did not succeed in discovering in it a trace of arsenic. He then dropped the subject, and probably would not have thought of it again had it not been that, about 1885–87, great excitement arose in Boston regarding arsenical wall-paper. Chemists in that city were kept busy day and night making analyses; the subject was brought before the Legislature with the intention to banish arsenic to the sea. He was then asked to express his views on the subject before a legislative committee, there stated what he had just said, and expressed the opinion that Boston was laboring under a fad. He did not dare show his face in that city any more. The chemists and physicians of Boston were committed almost as a unit to the idea.

The speaker here read cases reported by Harvard professors and others, in proof of illness or disease due to living in rooms papered with arsenical wall-paper, etc. In some instances, the symptoms said to be due to arsenical poisoning occurred in persons who had lived in the same rooms with unchanged wall-paper for seventeen to fifty years, or more.

An instance of this kind occurred in one of Boston's ex-mayors. The last year or two of his life he suffered from gastric and other symptoms which the physicians attributed to arsenical poisoning from wall-paper or the like, but unfortunately they made an autopsy and found cancer of the stomach. This rather perplexed the attendant physician, until it occurred to him that arsenical poisoning produced that kind of cancer. If arsenic was not found in the wall paper, cretonne, carpet, nor anywhere else, then physicians down that way would ascribe any obscure symptoms to arsenic which had entered the system in some unknown way. It was always arsenic. The speaker had come to the conclusion that it was practically impossible for people to tell the truth, even when they tried. Doubtless all the witnesses whom he quoted were honest in their belief.

The chemists speculated as to how arsenic got into the person's system. First it was by inhaling air containing particles of arsenic, but seeing that this theory would not account for a large proportion of cases, they began to insist upon it that the wall-paper gave rise to arseniated hydrogen. But wall-paper containing as much as a grain of arsenic to the square yard would, in a room of any dimensions, give off arseniated hydrogen in such minute quantity, if at all, that it could have no effect. Numerous chemical authorities could be quoted to show that it was utterly impossible for arsenic to volatilize from wall-paper at any ordinary temperature.

But wall-papers, as now manufactured, contained no arsenical pigments. It was true that some papers showed a little arsenic which entered with the material from which they were manufactured, but the quantity was extremely small. It should be remembered that the tests for arsenic were most perfect. One could detect the $\frac{1}{5000}$ of a grain, so that the statement that one had found a trace of arsenic meant nothing. It was true the old-fashioned papers used many years ago contained more arsenic, but they did not lose it; it was to be found in them on walls to day where they had remained a great many years. Most wall-paper was manufactured in New York and Philadelphia, and on inquiry he had found no workmen in the factories ever suffered from arsenical poisoning. Symptoms arose sometimes among persons who manufactured a destroyer of potato-bugs, but then they inhaled the fumes and the dust while sifting the substance containing arsenic. Few of them were affected, and as soon as an eruption appeared on the forehead or wrists they took an antidote and continued their work. They were grossly negligent. This showed that a greater quantity of the poison would have to enter the system to produce symptoms than could possibly be inhaled in

rooms whose walls were covered with arsenical paper, or the furniture of which might contain traces. With regard to their finding arsenic in the urine among the Bostonians, it was in minute quantity, as a rule less than $\frac{1}{300}$ of a grain, and might have entered with the vegetable food, baking powder, and various other ways, for traces of arsenic were present almost everywhere. A great many, if not all, mineral waters contained traces. The speaker said the symptoms of arsenical poisoning were not so specific that physicians could usually make the diagnosis of arsenical poisoning, and in illustration of this fact related the history of a man who, when his history was traced, was found to have gotten rid of seven wives, probably by slow arsenical poisoning, yet in only one was the use of arsenic suspected. The body of the victim having been embalmed with an arsenical preparation, a chemical analysis to establish his guilt would have proven valueless. He said incidentally that there should be a law prohibiting undertakers using arsenic in the embalming process.

A collation was served.

OUR LONDON LETTER.

(From our Special Correspondent.)

INFLUENZA AN INFECTIOUS NERVOUS FEVER—ITS NERVOUS SEQUELÆ — EXPERIMENTAL OBSERVATIONS ON THE AMMONIACAL DECOMPOSITION OF THE URINE—ANNUAL MEETING OF FELLOWS AND MEMBERS AT THE COLLEGE OF SURGEONS.

LONDON, November 7, 1891.

INFLUENZA has not entirely disappeared from our midst. Isolated cases still occur in the metropolis, and in the provinces outbreaks on a larger scale have taken place. The two papers brought before the Medical Society of London at its last meeting were, therefore, decidedly opportune. The first of these was by Dr. Julius Althaus, and in it the pathology of the affection was discussed at some length. The author expressed the opinion that the disease is not a catarrh, but an infectious nervous fever, and he referred all the symptoms to irritant poisoning by a "grippal toxine" of different centres of nervous force in the medulla oblongata. He attributed the peculiar fever to congestion of the thermolytic centre in the bulb produced by the irritant effect upon it of the "grippal toxine." The other symptoms of the nervous form of "grippe" were similarly referable to various centres in the bulb. "Grippal" catarrh and pneumonia were, he thought, due to congestion, or, in severe cases, to inflammation, of the nuclei of the fifth pair and the vago-accessory nerves in the bulb. The hemorrhagic tendency was to be accounted for by congestion of the vaso-constrictor centre in the medulla brought about by the "grippal toxine." The gastro-intestinal form, he urged, was produced by irritation of the vomiting centre in the bulb, and was occasionally transmitted to the splanchnic nerves by anastomoses in the cardiac plexus, and might then cause the symptoms of dysentery or choleraic diarrhœa.

Dr. Savage then read a paper on the "Neuroses of Influenza." He had, he said, seen in all some 54 cases of neuroses following influenza—33 in men, 21 in women. In 4, general paralysis of the insane resulted; in 20, melancholia; in 13, ordinary acute mania; in 6, delirious insanity; in 5, delirious mania; and in 6, mental weakness of some sort. Three-fourths of the patients recovered, and only three died. It was rare for a neurosis to present itself as the sequel of influenza in a perfectly healthy individual. All of his cases were suffering from some form of degeneration, or were under the influence of some potential cause of degeneration, such as alcohol or syphilis, or came of highly neurotic stock, and in some cases several of these factors were present at once. The patients who developed general paralysis of the insane had all shown signs, previous to the illness, of impending nervous breakdown. In the asylums influenza seemed to attack the sane more generally than the insane, and was equally marked by neuralgic pains in the limbs, etc. No definite relation existed between the severity of the attack of influenza and any subsequent neurosis. Any form of insanity might occur, but nervous symptoms of all kinds occurred quite independently of insanity. Simple neuroses, such as sleeplessness, neurasthenia, hypochondria, were common with or after an attack. The dangerous cases were of two classes—patients suffering from acute delirious mania, and those suffering from general paralysis of the insane. The treatment was general rather than special, and consisted in providing good food and surroundings, and administering hypnotics, etc.

On the motion of Dr. Sansom, seconded by Dr. B. W. Richardson, the debate on these two papers was adjourned.

At the Pathological Society, Mr. S. G. Shattock read a paper in which he gave an account of some investigations on the decomposition of urine which he had made. It appeared certain, he said, from the work of Pasteur and Lister, that healthy urine contained nothing which could bring about its own decomposition, and it was well known that in large hydronephrotic sacs the urine would remain clear and sweet for years; in extravasation there would be decomposition, but then the urine was usually foul beforehand. Several organisms had been found to produce decomposition of the urine. Two methods of investigating this subject were possible: 1, to isolate from the urine the organism growing in it and to identify it, and 2, to inoculate urine with other bacteria not usually found there, and see if they would produce ammoniacal fermentation. It was a question whether the hydrolysis of urea could be brought about by any method akin to the change produced in starches and albumins by superheating them, and Mr. Shattock showed that if urine were boiled for some time ammonia would be given off and a gradual hydrolysis of the urea would take place. If neutral urine were boiled, a precipitate of normal phosphates would occur, and if an acid urine were boiled for a sufficiently long time, the same result would follow. He had inoculated filtered and sterilized urine with active cultures of germs which had been grown in broth. In fully acid urine the common proteus vulgaris would not grow. Faintly acid urine, if heated discontinuously for four days, became amphoteric (from the development of free ammonia in it), and in this solution the proteus vulgaris grew slowly. He had tried both forms of streptococcus; the streptococcus bovis induced a faint ammoniacal reaction in the urine in which it was grown. The most marked results were obtained with the pyococcus albus and aureus; in forty-eight hours the latter produced an abundant fermentation with phosphatic deposit. It had usually been held that the micrococcus ureæ must be introduced from without, but these experiments showed that a suppurative pyelitis might induce an ammoniacal fermentation, and cause a precipitation of ammonio magnesian phosphate. The production of carbonate of ammonia by this fermentation was not of itself of so much importance in disease, but it served as an index of the putrefaction or suppuration that was going on. The carbonate of ammonia might, however, excite inflammation, and then the proteid products from the inflamed mucous membranes were added to the urine, and these furnished the toxic albumoses and alkaloids, which were elaborated by the agency of the micro-organisms. The possibility of an indirect pyogenic infection through the blood was not to be lost sight of, and in this way a simple catarrhal pyelitis might become suppurative, or a simple catarrhal cystitis purulent. He did not know at precisely what temperature the hydrolysis of urea occurred, but it certainly went on slowly at 60° C. A proper fermentation did not occur without the action of microbes, though a certain amount of decomposition of an unimportant kind might.

The usual annual meeting of Fellows and Members of the Royal College of Surgeons was held at the College on Thursday. The proceedings were very similar to those on former occasions of the kind. A resolution reaffirming the desirability of the members of the College taking some part in its management was passed with only one dissentient. Another resolution expressed regret at the Council having drawn up a scheme for a five years' curriculum without consulting the fellows and members. Complaint was also made that the Council had inserted in the report no reference to the general meeting held in May to consider the question of a university for London.

TREATMENT OF A "BAD COLD."

To the Editor of the Medical Record.

Sir: During the past twelve months I have read two sets of papers on the treatment of a "bad cold," in which the recommendations were peculiarly antiquated and musty. The suggestions contained in the first article appeared so out of date that I made a memorandum of them at the time, thinking it would be well to offer a criticism, and at the same time advise measures which would be more in keeping with modern therapeutics. The following notes cover the general plan of treatment:

1. The old-fashioned strong mustard foot-bath is advised at bedtime, the feet and legs being bathed up to the knees, and allowed to remain in hot water up to the knees for at least ten minutes. They are then to be wiped dry and patient put to bed at once.

2. A powder is then given containing a grain each of opium and ipecac and ten grains of antipyrine, which causes profuse diaphoresis, and gives the patient a good night's rest free from cough.

3. A vigorous friction of the chest with hartshorn or soap liniment is recommended to aid the action of the powder.

4. On the following morning the patient takes a good saline purgative, a glass of Villacabras or Rubinat mineral water, or two heaping teaspoonfuls of Sprudel salt.

5. As there is apt to be more or less bronchial irritation and cough for several days, severe enough to require treatment, to hasten recovery and promote comfort, a mild stimulating expectorant is indicated, like ammonium chloride. Take of

℞.	Ammonium chloride.....	5 grains.
	Spirits of chloroform,	
	Camphorated tincture of opium,	
	Syrup of ipecac..... ..... āā	5½ minims.
	Syrup of tolu, or syrup of wild cherry,	
	sufficient to make.....	1 teaspoonful.

M. Sig.: Take as often as required.

In lieu of the above, it is suggested that one-fifteenth to one-sixth of a grain of apomorphine chloride, two or three times daily, is sometimes equally efficacious.

Along with these instructions, it is stated that "probably ninety-five per cent. of cases"—such as that described, "would end in recovery without treatment."

In view of this latter admission, the question naturally arises as to the advisability of so much medication. If there is no pain in the side, no high temperature, no dulness on percussion, no bronchial breathing, and no portion of the lung-structure withdrawn from the exercise of its normal functions, with all the signs negative, wherefore this array of medicaments and remedial agents?

For the benefit of those members of the profession who are on the outlook for improvements upon the methods of by-gone days, and who so frequently hear the stereotyped assertion that "the babies can't take our medicine," I venture to offer a single remedy for the treatment of a "bad cold," that is far superior to all the baker's dozen just enumerated. Gelsemium is not only useful in those cases which would recover without medication, but is also efficient when formidable symptoms are present, and judiciously employed may be the means of averting an attack of pneumonia, pleuro-pneumonia, pleurisy, or other serious disease beginning in the form of a bad cold.

Gelsemium arrests profuse nasal secretions, quiets headache and neuralgia, subdues cough and pain, favors a re-establishmeut of the secretions, through its influence upon the skin, kidneys, and gastro intestinal tract. It reduces temperature and pulse-rate, promotes sleep, and creates a feeling of comfort and well-being without in any way approaching narcosis or destroying the oxygen-carrying capacity of the blood-corpuscles. By the use of this single remedy, much discomfort to the patient is avoided, digestion remains undisturbed, nauseating draughts are banished, the necessity for purgatives precluded, and all dangers of subsequent relapse practically eliminated; while recovery is prompt, perfect, and satisfactory in every particular. Ten drops of a reliable fluid extract (assayed), are dissolved in three ounces of water, and of this mixture the patient takes a teaspoonful every ten or fifteen minutes for an hour, then at less frequent intervals according to the effects produced. The plan is simple, the medicine harmless in the dosage recommended, and not at all unpalatable, and the claims for it can be verified almost any day of the week at this season of the year, by submitting the remedy to the crucial test of clinical experience.

John Aulde, M.D.

Philadelphia, November 14, 1891.

DR. KESSLER AND METHYLANILIN.

To the Editor of the Medical Record.

Sir: Since the publication of my paper on the therapeutic effects of methylanilin in the Medical Record of July 5, 1890, covering a large field of medical, surgical, and gynecological practice, such as cutaneous affections, ulcerations, purulent discharges of all kinds like otorrhœa, gonorrhœa, leucorrhœa; irrigation of the bladder in chronic cystitis, etc., I have received recognition and encouragement from professional brethren all over the country which amply repaid me for my small effort. On the other side, several well-known gentlemen have taken up the subject since, and discussed it in the press and in medical societies, fully corroborating my first impressions and experiences, without, however, giving the slightest credit to my prior work; which means lack of courtesy as well as lack of justice. As I do not care to rush into the press unless I have something new to say, I merely wish to add that a careful and conscientious observation of nearly three years has more than verified my enthusiastic predictions, and the statement then made, that methylanilin is the ideal antiseptic and pus-destroyer. "Chronic purulent discharges cease altogether, and sometimes at once, after a thorough exhibition of the antiseptic over the diseased parts—the microscope even failing to reveal any pus-cells"—I broadly stated in my above-mentioned paper, and this I have found in a number of cases to be literally true.

Adolph Kessler, M.D.

644 Lexington Avenue, November 21, 1891.

A Sigh for the Three-Bottle Days.—Dr. Mortimer Granville, in his letter on tectotalism, referred to in these columns a few weeks ago, said concerning what he believed to be the injurious effects of total abstinence: "I sincerely believe that incalculable harm has been done to the average human organism, with its functions, which we are wont to classify as mental and physical, by the spread of tectotal views and practices. There is less stamina in the life of the average Englishman now than there was forty years ago. He may live a little longer, but he is not so well able to resist the invading germs of disease or to recover from the debilitating effects of such an invasion as he was when good wine and sound ale formed integral parts of his daily diet."

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 15, 1891, to November 21, 1891.

WYETH, MARLBOROUGH C., Captain and Assistant Surgeon. The leave of absence granted on surgeon's certificate of disability, is extended three months, with permission to enter the Army and Navy General Hospital, Hot Springs, Ark.

GARDNER, EDWIN F., Captain and Assistant Surgeon. Relieved from further duty as Attending Surgeon and Examiner of Recruits in New York City.

RICHARD, CHARLES, Captain and Assistant Surgeon. Granted leave of absence for one month.

Official List of Changes in the Medical Corps of the United States Navy for the week ending November 21, 1891.

WOOLVERTON, THEORON, Medical Inspector. Placed on the retired list, November 13, 1891.

BRYANT, P. H., Assistant Surgeon. Detached from Coast Survey Steamer Gedney and wait orders.

JONES, W. H., Surgeon. Ordered to examination preliminary to promotion.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 21, 1891.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	34	10
Scarlet fever	124	15
Cerebro-spinal meningitis	0	2
Measles	45	4
Diphtheria	106	33
Small-pox	0	0
Varicella	3	0
Pertussis	3	6
Erysipelas	1	0
Mumps	1	0
Rötheln	0	0

Other Martyrs to Leprosy.—The *Medical Press* records the death of Father Testevuide, the founder of the Leper Hospital on Mount Fujii, Japan, which is as great a loss to that country as was that of Father Damien to the Sandwich Island leper community. The deceased missionary, finding in 1886 that there was no leper refuge in Japan, set to work and collected funds sufficient for the construction of the Mount Fujii Hospital, to the organization and maintenance of which he gave himself up entirely. Others have since taken up his apostolate, and there are now three leper hospitals where fifteen years ago there was none. Recently also another priest, who had consecrated his life to the service of lepers even before Father Damien, died in Surinam. His name was John Bakker; he was born in Holland, and was a member of the Redemptorist Order. His attention was called many years ago to the neglect of the lepers in the countries along the Caribbean Sea, and especially in Dutch Guiana, and he proceeded to Batavia and gave himself up to the care of these outcasts. He had been a leper for about nine years.

The Punishment for Rape.—The unlawful taking of the hymen has in all times been visited by the most severe punishment. The penalty was death among the Jews, if the maid was engaged. If a man lay with a betrothed damsel in the city, they were both stoned. If in the country, the man only. It was reasoned that in the city the maid could cry out and have help; in the country she could not. Among the Athenians, Romans, ancient French, and the English, and in many of the United States, in their early days, the offence was punishable with death. In New York, by the law of 1787, rape of a child under ten years of age was punishable with death. In 1810 it was changed to imprisonment for life. In Illinois and Massachusetts the punishment was death. In Texas it is still a capital crime; and only as long ago as April, 1888, a man was hanged, not lynched, at Gainesville, Tex., for rape. In the Isle of Man, in "ye olden time," there existed a very wise custom. The criminal was brought into a public place, and his victim was given a sword, a whip, and a ring, and his punishment left entirely in her hands. She could kill, whip, or marry him. Among the old Welsh, he who robbed a maiden of her hymen, there being two witnesses to the same, was required to present his sovereign a piece of silver as high as the sovereign's mouth and as large as his little finger.—DR. E. S. MCKEE, in St. Louis *Courier of Medicine.*

Who Struck Billy Patterson?—We see it announced in a secular paper that Dr. Alban S. Payne, formerly of Fauquier County, Va., now of St. Louis, Mo., claims to be the man who struck the genuine and original Billy Patterson. Dr. Payne claims that it occurred in this city in 1848, when a crowd of roughs coming along the street met the doctor and some companions and jostled him off the sidewalk. The fellow was a stalwart butcher, but Dr. Payne let him have it from the shoulder, and "hypnotized" him so terribly that the astonished crowd asked in utter amazement, "Who struck Billy Patterson?" They were promptly informed, in a stentorian voice, that "*I* struck Billy Patterson." This answer was satisfactory to all parties concerned.—*Southern Clinic.*

AN EARLY METHOD OF DIAGNOSIS IN DIPHTHERIA—WITH DEMONSTRATIONS.[1]

By LOUIS FISCHER, M.D.,

ATTENDING PHYSICIAN TO THE CHILDREN'S DEPARTMENT OF THE GERMAN POLIKLINIK, NEW YORK.

THE importance of differentiating between diphtheria and tonsillitis follicularis, and the numerous mistakes which are daily made in both, is the reason that I desire to call your attention to the subject. The question also of isolating the different members of a family is of such importance, and the chances of infection so great, that any communication which could tend to establish a positive diagnosis is surely not to be discarded.

The first thing to establish in the way of a differential diagnosis, is to bear in mind the similarity of symptoms of both diseases, especially, however, of: 1. The position and most favored locality of both affections, which manifest themselves usually on the tonsils. 2. The similarity in appearance of the exudations, which sometimes are grayish-white, grayish-yellow, gray, and green. 3. The temperature. 4. The swelling of the lymphatic glands. 5. The general constitutional disturbance peculiar to both.

In diphtheria the presence of albumin in the urine should not be overlooked, although Henoch says "that its absence does not speak against diphtheria." He further says: "I do not attach any importance to the presence of a high temperature nor to the swelling of the lymphatic glands, as they are common to both diseases."

When we read over the combined works of our most prominent observers, among these Henoch, Baginsky, Oertel, Heubner, Klebs, Löffler, Jacobi, Prudden, etc., we find that all agree that diphtheria is caused by a bacterium which is a "bacillus," and for the discovery of which we are indebted to Löffler. Carl Fränkel, in his text-book on "Bacterial Diagnosis" for 1891, says: "In the course of examinations the statements of Löffler have now been positively proven, and besides, numerous other observers, among them Babes, Kalisko, Paltof-Zarniko, D'Espire, Escherich, have shown the constant presence of Löffler's bacillus in all typical cases of diphtheria, and have also found that this same bacillus exists only in this latter affection, viz., diphtheria.

Roux and Yersin have finally found, by subcutaneous injections of these bacilli into animals, that they can reproduce the same toxic symptoms peculiar to man which Löffler was not so fortunate in doing, and could produce typical diphtheritic paralysis; so that we can positively accept Löffler's bacillus as the true cause of human diphtheria.

How different are the reports on this latter subject prior to 1884. Especially is this seen by a reference to Henoch in 1881, who says (on page 618): "The microscopical examination of the membrane in question does not give any positive criterion, because epithelium, amorphous masses, and bacteria are found in both cases, to positively differentiate between diphtheria and tonsillitis follicularis."

A positive diagnosis can, however, only be made after not only the tonsils, but also the ends of the soft palate, the uvula, the corners between these and the velum, and the descending arcades of the gums are covered with white plaques.

Dr. A. Jacobi, in his "Treatise on Diphtheria," 1880, says: "I am bound to say, however, that anxious though I be for a possible future success of a parasitic theory of nosogenesis, I have not been able to change my attitude in regard to the prevalent bacteria doctrine of diphtheria. I cannot look upon the bacteria epidemic in the medical journals, particularly of Germany, with the hasty conclusions and gratuitous assumptions of scores of experimenters and writers, as anything but a calamity which I trust is but temporary."

Ten years later he says, in a paper read before the Tenth International Medical Congress in Berlin: "Still, the time has not come, when the diagnosis of a case of diphtheria in the daily run of practice can be verified by the microscope, nor is the nosogenesis of diphtheria settled beyond a doubt. Löffler's staphylococcus has been found so often and so regularly, that it is hardly possible to deny the causal connection between it and the cases of diphtheria in which it was found. Still it has been found in the oral mucus of a healthy child, once by Löffler, and again by Babes and Von Hoffman; and Löffler himself proves particularly, through the death of inoculated guinea-pigs which ensues, though the result of the inoculation remains local, that the real cause of death must be looked for in a ptomaïne. On the other hand, in America, where we have had diphtheria uninterruptedly this last one-third part of a century, T. Mitchell Prudden found no staphylococcus, but a streptococcus which he claims to be the cause of all cases of diphtheria examined by him."

Now, there is diphtheria as a result of staphylococcus or a ptomaïne resulting therefrom, there is diphtheria as a result of a streptococcus, or rather a ptomaïne resulting therefrom; now, what does it all mean? It signifies that the diphtheritic membrane, and one or more of the symptoms of the diphtheritic process, with its mild, or severe, or fatal course, may be dependent on different micro-organisms, in the way in which Gerhardt suggested it before the Congress of Internal Medicine, some years ago.

I am glad, however, to announce that now two of the greatest observers of America and Germany, Jacobi and Henoch, agree that diphtheria is caused by a micro-organism which is Löffler's bacillus.

In the last edition of Henoch's text-book for Diseases of Children, 1890, page 710, we find the following statement: "Whether the result of Roux and Yersin obtained after experimenting with the bacillus described by Klebs and Löffler is the specific cause of diphtheria, remained to be proven. The examinations also of Escherich are not conclusive. We can, however, according to the latest examinations of Löffler, and also the latest results obtained by Brieger and C. Fränkel, positively state that the Klebs-Löffler bacillus, and more so the toxic albuminoid produced by the same, is the real cause of the mischief in diphtheria."

Baginsky, 1887, p. 189, in speaking of the diphtheritic investigations of Letzerich, Oertel, Hüter, Klebs, Heubner, and Löffler, says: "It seems that the last named micro-organism and not the presence of the cocci, is the cause of the pathogenesis in diphtheria, and that these cocci are only to be looked upon as a secondary condition."

[1] Read before the German Medical Society, at the Academy of Medicine, New York, November 2, 1891.

It has been therefore positively proven that diphtheria is caused by a bacillus first described by Löffler, and which has the appearance of small, slightly curved rods about as long as tubercle bacilli, and twice as broad; the ends are at times swollen, spores have not been found. They do not possess any movement and do not liquefy gelatine, and have no spores. The bacillus is not found in the blood of the patient, but only in the pseudo-membranes, and most readily in the oldest portions of the same. In a dried condition, *i.e.*, in pieces of pseudo membrane, the bacillus can be cultivated after three or four months, and it has been known to retain its vitality in one case as long as five months.

In the mouth and pharynx there has been occasionally found a bacillus resembling morphologically and in the culture the Löffler bacillus, which, however, is not virulent; it has therefore been named the pseudo-diphtheric bacillus. This last-named bacillus has been studied by Löffler and Von Hoffman. The differentiation is easy, as the reaction of alkaline bouillon is not changed by the pseudo-diphtheric bacillus, whereas in the presence of the real diphtheric bacillus (Löffler) the reaction is changed to acid.

In his paper on "Follicular Amygdalitis," A. Jacobi, on November 16, 1886, read before the New York Academy of Medicine, says:

Professor B. Fränkel read a paper before the Berlin Medical Society on "Angina Lacunaris and Diphtheritica," and says: "Such cases, however, are so rare that I cannot agree with Jacobi in this, that the spreading of diphtheria is attributable to angina lacunaris. Still there is a possibility that diphtheria may be spread through angina lacunaris, and therefore I deem it proper as a measure of caution to isolate cases of angina lacunaris."

A. Jacobi answers this with the following: "Nor do I say that every case of follicular affection of the tonsils is diphtheria, and that diphtheria in general is spread by follicular amygdalitis in general, but I claim that the name of follicular or lacunar amygdalitis is but a subterfuge for a lack of a correct or a complete diagnosis. This could, however, have been easily proven by a bacteriological examination of the exudation in question."

Heubner, in "Yearbook of Pædiatrics," vol. xxxiii., p. 402, speaks of cases where after a three days illness of angina lacunaris, diphtheria develops. In my opinion these cases would never have been diagnosed as angina lacunaris if a thorough bacteriological examination would have been made."

In a paper read at Philadelphia in 1888, A. Jacobi says: "What has been called follicular amygdalitis or tonsillitis, is diphtheria in many, perhaps most instances."

A. Caillé, in a paper read at the Tenth International Congress at Berlin, 1890, said: "Of fundamental importance in the study of the infection of the naso-pharyngeal spaces, is the statement of A. Jacobi, made thirty years ago, that it is almost impossible clinically to differentiate between tonsillitis follicularis and diphtheria."

In order to be positive if we have diphtheria in a given case, we must have the following: 1, a sterilized scissors; 2, a sterilized forceps; 3, a sterilized test-tube; 4, 6 to 8 agar-tubes; 5, incubator or brood-oven.

The method of examination is about as follows: We must have good light, so as to secure certainty. We then place the child in the same position as for intubation, and if restless can secure patient with a gag. We then cut a small portion of the pseudo-membrane after having seized it with the forceps, a very small piece as large as a pin head is enough to make a stroke-culture on agar or blood-serum which has solidified in an oblique position, and is then placed in the incubator.

The ordinary temperature is enough to develop the pathogenic bacteria if present, but as it is important to develop the bacilli as speedily as possible, it is advisable to put the agar-tubes into the incubator or brood oven at a temperature of 70° to 107° F. (20° to 42° C.).

After considerable experimenting I have been able to cultivate enough cultures to determine a diagnosis in about twelve hours; the rule is, however, that no more than eighteen hours are required, so that if I inoculated my agar in the evening, I could positively have my culture the following morning. These colonies can, if the macroscopical examination is not satisfactory, be immediately examined in the hanging drop, which is easily made by mixing a drop of sterilized water with a very small quantity of a colony removed by means of a platinum-pointed needle on a cover-glass and examining it microscopically. The edges of the concavity of the glass slide are smeared with vaseline and the slide inverted over the drop; the cover-glass sticks to the smeared slide, which when turned over, holds the drop in the depression covered by the cover glass, thus forming an air-tight cell; here the drop cannot evaporate.

The narrow blender shutting off the Abbe condenser, and a drop of oil of cedar being put on the cover glass, our specimen is ready for the microscopical examination. Or, if we do not wish to see by the last-named method living bacilli, then we can take on a platinum point a very small part of a colony and stroke it on a cover-glass, allow it to dry thoroughly, then stain it with ordinary methylin blue staining, and examine it with Canada balsam. By this method we can study the bacillus, if it be present.

I have a number of specimens here which you can examine; they are from a child which I attended, and one of the specimens is from another child sick with diphtheria, under the care of Dr. Hilke, at the German Poliklinik of this city. The specimens have been prepared according to the above-mentioned methods. You can find the Löffler bacillus very easily and also very plainly. If, however, we wish to be still more positive of our diagnosis, and do not wish to depend on our macroscopical and microscopical examinations, I have found the following method most applicable.

It is well known that certain animals are very sensitive to diphtheria, and others, rats and mice for example, are not affected at all. Here you can see a white mouse which, on October 19th, I had inoculated subcutaneously in the skin of the back, immediately over the lumbar region, with a virulent culture of diphtheria bacilli, and you can also see that the animal enjoys perfect health. From the same culture I inoculated a rabbit, on which I first performed tracheotomy, on two places in the trachea, and the rabbit died in about eighteen to twenty-four hours. I cannot say exactly how long after the inoculation death occurred, because the animal expired during the night.

The post-mortem examination of the rabbit showed: 1, serous effusions in the pleural cavities; 2, which I consider of the utmost importance, yellowish-gray plaques in the trachea; I immediately took a piece of these latter membranes, and made some stroke-cultures on agar, and after sufficient growth found the Löffler bacillus. The preparations which I now show you are from the trachea of the latter-named animal. I also show you here a guinea-pig which I inoculated in the vagina with a small quantity of a virulent culture of diphtheria. You can plainly see the membranes on the places where I inoculated. The mucous membrane shows an inflammatory, necrotic condition. From these membranes I also received, by making a stroke-culture on glycerine agar, very large colonies, which could, by the previously described staining method, be easily recognized as diphtheria bacilli.

I desire furthermore to call your attention to the cause of death of these animals, which was "diphtheritic paralysis," and this guinea-pig plainly shows this paralyzed condition on the extremities. Where I have used the words agar, or agar-tubes, I mean an agar with an alkaline reaction which contains six per cent. of glycerine, in other words a so-called glycerine agar.

In the Kaiser and Kaiserin Friedrich Children's Hospital, in Berlin, both glycerine agar, and blood-serum, are

used as culture media. For human serum, fluid from hydrocele-pleuritic effusions, etc., are used. Such is, however, only possible in a large hospital, as for example at the above-named one in Berlin, whereas, here in the city, I had to content myself by procuring serum from beef-blood from a slaughter-house, located at Forty-fourth Street, East River, of this city.

For the kind assistance at the anæsthesia of the animals, and for numerous other favors, I, with your permission, would express many thanks to Dr. Biggs. In connection with the above, I desire to state that the practical application of the method described this evening, I first saw from Dr. Adoiph Baginsky in Berlin, during my service at the children's hospital; I also had an abundance of opportunity afforded me to see diphtheritic cases daily with Dr. Baginsky while he made his rounds. I have also seen severe forms of paralysis developing weeks after a mild form of diphtheria in children, showing a light form of infection. Furthermore, I have had the opportunity of observing that in children, which had been isolated for diphtheria, but where no colonies developed after the usual inoculation of our culture tubes with membrane of supposed diphtheria, that such cases invariably proved to be tonsillitis follicularis, or something else than diphtheria. I do not believe in a streptococci diphtheria as it is described by Prudden in the *American Journal of the Medical Sciences* for May, 1889, as I invariably found the Löffler bacillus in all cases of diphtheria. I have, however, found as previously stated the Löffler bacillus in conjunction with streptococci. It is well known that bacteria are normally found in the mouth, so I have several times experimentally inoculated mice with my sputum subcutaneously, I never could find bacilli; I however found micrococci, of which species the streptococci and staphylococci predominated. If you take some of the morning sputum before cleansing the teeth, and hypodermically inject a mouse, you will find that death usually ensues in twenty-four hours from a septicæmia. On July 15th, this year, I injected a mouse in this manner at the Hygienic Institute at Berlin, and found on post mortem examination only streptococci in the heart blood, as also in the organic fluids. On further examination of the sputum, I discovered that it contained large numbers of streptococci. From this it is easy to explain why we sometimes have a mixed infection, *i.e.*, the Löffler bacillus combined with streptococci; as the body contains several micro-organisms in the sputum, normally in the nasal secretion, in the urethra, and in the vaginal secretions in healthy persons, so it is easily explained why, under certain conditions, be they cold, trauma, in other words any subnormal condition, the reactive powers of the body are lessened to such a minimum that pathogenic bacteria can, and do, enter, causing different pathogenic conditions.

From this it is easily explained why by an invasion of diphtheria in certain families one child may be infected, several may not; or the reverse, several might be infected and one be spared.

The occasional occurrence of streptococci in the cultures can only be regarded as an accidental mixed infection or as a complication, as, *e.g.*, pneumonia, pertussis, etc., which might very often be the case. As I have very often found streptococci as secondary with the Löffler bacillus, in all cases where I have had the coexistence of diphtheria with a complication, and as most of the cases were of a fatal character, so I have come to look at the presence of the Löffler bacillus with the streptococci as a bad symptom, and consequently would give a bad prognosis in such cases. Prudden reports in 1889, 24 cases of diphtheria, in which he found streptococci in 22 cases; Löffler's bacillus he did not find in any of these cases; I will not criticise his results, for on April 18, 1891, he reports in the MEDICAL RECORD 12 further cases, wherein he finds the presence of the Löffler bacillus in 11 cases. In the same article he also describes all the published cases in Europe and America to date, in all 316 cases, wherein the Löffler bacillus was found in 302 of the latter. We can therefore only state that, although Prudden details his experiments, that the 24 cases described by him in 1889 cannot be looked upon as cases of true diphtheria.

It is therefore, gentlemen, as I have shown you, not difficult to make an early positive diagnosis by means of bacteriological examination. So also are the various manipulations so simple, that I am positively convinced that every physician can with very little trouble master the situation.

In this city, where we have so many laboratories, each and every physician can procure the necessary utensils, and it is worth while to complete the clinical examination by a bacteriological examination.

Finally, I very much desire to see in a short time, as in Europe, especially as in Berlin, in connection with every hospital a bacteriological laboratory, no matter how small, to which every physician should have access, and wherein all necessary appliances to aid everyone for the completion of the diagnosis should be placed at the disposition of the profession in general.

For numerous favors and friendly advice I desire to express to Dr. Ferguson, pathologist of the New York Hospital, my sincerest thanks, as I completed all of my experiments, as also my animal experiments, in the bacteriological laboratory of the New York Hospital.

PNEUMONIA AS I SEE AND TREAT IT.[1]

BY A. A. YOUNG, M.D.,

NEWARK, N. Y.

THE subject to which I would call your attention to-day is pneumonia, with special reference to its treatment and the results obtained by such treatment. Since my method differs somewhat from that of my co laborers, and since the results attained are to me highly satisfactory, I deem it not only my privilege but my duty to make that method known, that it may be still further investigated—further than it is possible for me to do to prove its truth or falsity.

The term pneumonia I regard as a misnomer, since it may imply and include all inflammatory affections of the lungs, induced by any cause, or by any excitant. It seems as rational to call a corn pneumonia and treat it as such, as to call and treat a common cold or any local congestion of the lungs by and under the pneumonic name and method. Of our diagnosis we must be reasonably certain, or our observation and treatment, so far as the world is concerned, comes to naught.

The theory that pneumonia is the result of the deposition and development of a specific germ may be true, but the deposition and development depend in a measure on atmospheric and other influences. Most of the cases which have fallen under my observation occurred when the wind was in a northeasterly direction, and that was cold and laden with an abundance of moisture. This seems, however, to have been a condition and not a cause for the development of the pneumonic poison. To define what that poison is, and what relation it sustains to the atmosphere, would be as difficult a task for me as to define what life is, and what relation it bears to the body; yet such a thing, substance, or force exists as

[1] Read before the Central New York Medical Society at Buffalo, June 2, 1891.

life, and it does have a relation, though undefinable, to the body.

Pneumonia to me means but one distinct affection, having similar pathological changes in each case, though the objective signs and symptoms may vary much in character, depending on the progress and severity of the disease.

Before proceeding farther it may be well for us to recall some of the more prominent features of a typical case of pneumonia; thus we shall meet on common ground, and the reasons for treatment shall more clearly appear.

First comes the initial chill, which is not repeated, followed by engorgement of the affected portion of the lung, this passing gradually into red hepatization, and resolves itself into gray hepatization still later. Pyrexia begins or immediately follows the chill; the skin is dry and hot; the pulse is rapid; there is labored breathing; the tongue is dry and parched, and there is a diminution in the amount of saliva excreted; a little later comes the hacking cough, with a moderate amount of expectoration of a gluey nature and rusty color; headache, sleeplessness, and delirium are the marked nervous symptoms; the urine is scanty, high-colored, and contains a large amount of urea and uric acid, and occasionally albumin, while the chlorides are largely absent, but curiously enough, are found in the sputum. From observation I am led to believe that the delirium, restlessness, and headache are due in a large measure to the abnormal amount of urea in the system. The headache, restlessness, sleeplessness, and slight delirium, coupled with diarrhœa, which sometimes occurs, are signs which indicate the severity of the disease only—signs which, when isolated, may lead to the diagnosis of that disease of which I have heard, but never seen, "typhoid pneumonia," and of which the patient may perhaps die, of "heart failure."

It is true the action of the heart is interfered with and the tendency toward failure is pronounced; but this tendency is due, not to loss of power in the heart-muscle, or to local lesion, or to fatigue, but is directly attributable to the action of the pneumonic poison. The precision with which this disease begins, the regularity with which it progresses, and the abruptness with which it terminates, certainly indicate it to be a systemic, self-limited disease. What this particular poison is I do not pretend to say, but the elimination of it from the system, or its destruction otherwise, is what is indicated and desired, and it remains with us to solve the question, how?

That there is a relation between the urea or urates of the system and the pneumonic poison, can scarcely be questioned, for the severity of the malady can almost be measured by the abundance of urates present. I would here venture the statement that we lessen the severity of pneumonia in proportion as we diminish the amount of uric salts in the system. The presence of albumin in the urine is directly traceable to the presence of this agent; the rule is, the greater the amount of urea the greater the amount of albumin.

To lessen the amount of the urates is the principal object, in my mind, of the treatment I am now about to suggest. It is to be observed that priority or originality of treatment is not here claimed. It is believed that others have previously used the drug of which I am about to speak, in similar cases, but its non-acceptance by the medical profession is due to causes that are to me unknown. Suffice it to say, that the conclusions here reached are based upon observations made during the last six years, or since 1884.

The drug which I have almost exclusively relied upon to combat this malady is jaborandi, or better still its alkaloid, pilocarpine, since from the latter we get a more definite and uniform action. Some of the physiological effects of this drug will now be briefly noted, then the "my why" of prescribing it will become more apparent.

Within twenty minutes after the administration of a full dose of this drug—perhaps ten minutes would be sufficient if administered by the hypodermic method—there is first a flushing of the face and skin of the entire body, which is quickly followed by profuse perspiration beginning on or about the forehead, and coupled with this comes intense salivation, which usually lasts from two to four hours, though I have observed a continuation of it for over twelve hours from one administration. The frequency of the pulse is lowered, but its force is not diminished. No depressing effect has ever been observed by me on the action of the heart, save the lengthening of both its systolic and diastolic actions. The amount of urine is largely increased, and the relative amount of urea which it contains is also proportionally increased. It has been proven that the perspiration contains urea in abundance. The drug possesses also slight narcotic and emetic properties, and to the former may be attributed, in a measure, the decline of delirium upon its administration. With the sweating comes well-marked diminution of temperature, reaching its minimum at the close of the sweating period, some six hours later. It will require from six to twelve hours more to show a very marked rise in temperature. As an anti-pyretic alone, in pneumonia it appears to me a valuable remedy and well worthy of a trial.

Having now given some of the diagnostic signs and symptoms of pneumonia; having given some of the pathological conditions which exist in typical cases; having even more than intimated the drug on which I place my main reliance; I will now try to show that we may realize in practice what we devise in theory, by relating a couple of cases that have come under my observation and treatment, and of which I have a comparatively full record.

Case I.—December 27, 1889, I was called to see J. D——, aged about twenty-eight years, from whom I received the following history: While in a neighboring village, December 24th, a few miles from his home, he was seized with a chill of moderate severity, but believing this to indicate only a cold or possibly "La Grippe," little attention was paid to it, he taking only what appeared to be an ordinary licorice mixture. As he gradually grew worse, the cough becoming more troublesome, and he showing unmistakable signs of fever, I was called in on the evening of the date above mentioned, some sixty hours after the initial chill. The pulse was rapid and marked 116; breathing slightly labored and 26; temperature, 103⅕° F. There was a persistent, hacking cough, and a small amount of rusty-colored expectoration. Physical examination revealed the fact that I had a pure and uncomplicated case of pneumonia. I will not weary you with details, but take my patient where I found him, sitting up in his chair, with a temperature of 103⅕° F.; respiration, 26; pulse, 116 on the third day of the disease. He was ordered to bed and one-fourth grain of muriate of pilocarpine was administered; if this did not produce perspiration in one hour, one-eighth grain more was to be administered. The first portion proved quite sufficient, as I afterward learned. Profuse sweating and salivation occurred in about twenty minutes and continued for nearly twelve hours, at the close of which time he received a thorough rubbing with a dry towel. Sparteine in one-twentieth grain doses was ordered every four hours to quiet the irritable heart. I saw him again about twenty-four hours later, and found the skin still bathed or covered with considerable perspiration, and cool and silky to the touch. Dyspnœa was less marked than at my previous visit; the tongue was more clear, and the patient appeared more bright. Pulse, 98 and regular; temperature, 100⅕° F.; respiration, 22; cough still exists, but is less tedious; expectoration more easy, but still containing blood. The urine, which was previously scanty and dark-colored, was now increased in quantity and lightened in color. I then ordered pilocarpine to be given night and morning in doses of from one-eighth to one-fourth grain, as might be required to produce free perspiration.

Carbonate of ammonia, three grains, was now added to the sparteine, and given three times daily. From this treatment I made no change until the crisis was reached. The evening temperature remained 100° to 100½° F.; pulse from 96 to 98; and respirations, 20 to 21. I saw him about two hours after the crisis had been reached, on the afternoon of the seventh day. The skin was bathed with a cool perspiration; the pulse, 70; temperature, 97⅘° F.; respirations, 20, and the tendency was toward a natural sleep. The tongue was clean, but more red than natural. Pilocarpine was now discontinued, but the carbonate of ammonia and sparteine were retained. Two days later the carbonate of ammonia and sparteine were discontinued, and iodide of iron and cod-liver oil were substituted. He was kept on this treatment for about ten days, soon after which he returned to his accustomed duties, feeling as well and strong as he did previous to his illness.

Case II.—January 2, 1890, I was called to see J. C——, aged about twenty-five. He was taken with a chill, December 29, 1889, which he attributed to a cold. As he was not relieved by the ordinary remedies, I was sent for on the day mentioned. I found a temperature of 102½° F.; pulse, 112; respirations, 23, and other unmistakable signs of pneumonia. This might be called a typical and uncomplicated case at the outset; what developed later were mere side issues, and largely foreign to the case in hand. I found him sitting up, as in the case just mentioned. The nature and severity of the disease were pictured to him, and he was ordered in bed; I then prescribed one-fourth grain muriate of pilocarpine, to be repeated in one hour, but no more to be given till morning, when, if perspiration had not been profuse, to administer one fourth grain; if it had been profuse, to administer one-eighth grain. Digitalin, one one-hundredth of a grain, was given four times daily. I saw him again about twenty hours later; the body was still bathed in profuse perspiration; pulse soft and 100; no headache or pain of any kind; mind clear. Pilocarpine, one-eighth grain, ordered each night and morning, and digitalin four times a day; a teaspoonful of brandy three times daily was also ordered, with milk. Expectoration became easy and moderate in quantity, containing some blood. From this date and until the crisis was reached there was no perceptible change, and the treatment was not varied. The crisis occurred in this case also at the close of the seventh day, dating from the chill. I saw him some twelve hours later, when his pulse was 70; respirations, 19; temperature, 98⅕° F. For two days succeeding this he was apparently on the road to a rapid recovery, when he was seized with a severe attack of rubeola. This progressed favorably and had reached the period of decline, when he had a severe chill, followed by a couple of lighter ones; I was immediately sent for and diagnosed capillary bronchitis in the lung which was previously unaffected. Fearing I might again have a return of pneumonia, and desirous of thwarting it, I continued the use of the pilocarpine and digitalin with other remedies, and kept the body bathed in a moderate amount of perspiration. The young man made a good recovery, with no indications of a return of the original malady, and during the year that followed he has enjoyed better health than ever before.

These two cases, to which I have but briefly alluded, are not isolated ones. The same phenomena have invariably appeared in other cases where pilocarpine was administered. Can it be a coincidence? Is the theory tenable?

May not the pneumonic germ—name it what you will—be an agent, the office of which is to destroy the abnormal products of the system, products that produce those objective symptoms which, when taken collectively, we call pneumonia?

Let us call a halt occasionally, and ask ourselves the question. Are there not other lines of thought and of investigation than those of bacteriology, and equally as valuable? If so, then there must be other remedies equally as good, equally as valuable as the germicides.

THE PERINEUM: HOW TO PRESERVE IT.

By N. W. RAND, M.D.,

MONSON, MASS.

The perineum, strictly speaking, consists of all the soft tissues which close the pelvic outlet; yet, to the obstetrician, that part in the female filling the triangular space between the vagina and rectum, and known as "the perineal body," is all that is of special importance.

This consists of the integument, cellular tissue, perineal fascia, part of the sphincter ani, sphincter vaginæ, and transversus perinæi muscles, the posterior portion of the triangular ligament, also part of the levator ani et vaginæ muscles, and the recto-vesicular fascia. In this body the several muscles and fasciæ mentioned blend into one firm fibrous tissue which is known as "the tendinous centre of the perineum." The functions and importance of this portion of the female perineum are obvious. It includes the muscles which control the orifices of the rectum and vagina; to a considerable extent it separates these passages, furnishing support for both, and through them indirectly aids in sustaining all the pelvic and abdominal viscera.

Indispensable as this structure is, we all know that its integrity is imperilled with every act of parturition. It seems as if Nature had here come nearer to making a mistake than in any other part of the human economy. And yet perhaps the fault is less in Nature than in our own civilization, which has so unequalized the development of various parts as to render them no longer complementary. The lower animals as a rule are not liable to such accidents, and, so far as I have been able to ascertain, they are of very infrequent occurrence among the aboriginal races of men. It is only among civilized people that we find the fœtal head developed out of proportion to the female passage. That perineal lacerations are a common cause of vaginal and uterine prolapsus, uterine retroversion and retroflexion, together with innumerable nervous and functional disturbances throughout the body, no one can doubt.

To obviate this long train of troubles accoucheurs have from time to time devised various methods of protecting the perineum from the injuries incident to childbirth. Ramsbotham and others recommend making firm pressure against it with the hand as the fœtal head descends. Leishman and Smith claim that this irritates the nerve-supply of the parts, and by reflex action excites the womb to more vigorous contractions, thus lessening the time for dilatation and tending to bring about the very accident they are striving to avert.

Goodell would have us introduce two fingers into the rectum, and with each pain draw the whole perineal body forward over the child's head. This undoubtedly would favor dilatation, as it increases the time during which force is exerted, but it retards the progress of labor and is disagreeable alike to physician and patient.

Playfair approves of the principle involved in Dr. Goodell's method, and in the following language advises a modification of it: "When the head is distending the perineum greatly, if the thumb and forefinger of the right hand are placed along its sides, it can be pushed gently forward over the head at the height of each pain, while the tips of the fingers may at the same time press upon the advancing vertex so as to retard its progress if advisable. By this means the sudden and forcible stretching of the perineal structures is prevented, and the chance of laceration reduced to a minimum, while Nature's mode of relaxing the tissues by dilatation of the anal orifice is favored." This seems to sound very plausible, but I fail to see how relaxing the tissues an inch and a half back of the vaginal opening is any relief to the tissues at the very edge of that opening. It seems to me that it would allow the head to descend upon those shortest fibres more suddenly, and so place them in greater peril. Still we must confess that this method has more to commend it than either of the others which have been mentioned.

Two years ago last July I attended a lady over thirty years of age in her first confinement. She was small in stature, closely built, and, as I had anticipated, the labor was tedious. For three or four hours I fully expected to be obliged to resort to the use of the forceps. But, delaying, as I usually do, as long as practicable, I occupied my time in dilating the vaginal orifice, which was about the smallest I have ever found; this I did by inserting two fingers and making steady traction directly back toward the coccyx. It was, of course, tiresome both for the patient and myself, but I was well rewarded for my trouble by seeing the large, long-delayed infant's head emerge from the vulva without a tear. I watched the process; the perineum slipped over the face and clasped the neck tightly, and after the birth was completed it was found to be perfectly intact.

At first I was surprised and couldn't understand how it was possible, but after reconsidering the whole case concluded that what I had termed good luck was simply the result of my persistent stretching. I tried it again with similar results; and, as opportunities have occurred, I have been trying it ever since. Having thus seen its practical results, and later, its reasonableness, I am now thoroughly convinced that in something of this kind consists the best method of protecting the perineum. One great advantage it has over even the best of the other methods referred to is, that in the accomplishment of its purpose it facilitates, while they retard, the progress of labor—a consideration of no small importance to the busy practitioner.

We all know that muscular and connective tissue will tolerate almost any degree of stretching, provided the force be applied with uniformity and for a sufficient length of time, just as the anus is dilated to admit the passage of the hand and arm in operations upon the lower portions of the bowel, and the female urethra is dilated when the bladder is to be explored.

There is no tissue of the body that will not yield to pressure when persistently applied. The bones themselves are no exception to this rule, as is illustrated every day in the facility with which dentists, by means of the elastic wedge or rubber band, move the position of teeth about at their pleasure. I do not believe that there was ever a vulval aperture so small, no matter how rigid the perineum, that it could not have been dilated, without laceration, to the full capacity of the pelvic outlet if the dilating force had been gradually applied for a considerable length of time.

There lies the whole secret, and in it we see the reason that we almost invariably tear the perineums of primiparæ in instrumental deliveries. We don't wait long enough for the tissues to stretch, and in half the cases Nature by herself doesn't wait long enough, and the same results follow.

Now, admitting the correctness of these premises, the indications for treatment are very plain, viz.: Anticipate the passage of the child by the early and thorough dilatation of the vaginal orifice. That something in this direction can be accomplished by the fingers alone I am sure. That still more might be done by some appropriately applied dilating instrument I am equally certain. Here is an opportunity for some physician of mechanical genius to benefit himself, and the whole motherhood of man, by devising the proper instrument.

But some will say, "There is nothing in it. It was recommended more than a hundred years ago by Smellie and Puzos and Roederer, and if it had had any merit it would have found its place then in obstetrical practice." I beg to differ. I grant that the physicians mentioned advocated something of the kind, but I cannot discover that it was ever given a fair trial. Glimpses of many of the most important truths now known to us have been caught and lost again by different individuals in ages past.

Anæsthesia, the *sine qua non* of modern surgery, was essentially discovered and forgotten half a score of times before its present introduction by Dr. Morton. Many of our remedies and methods of practice have shared a similar experience. No art can be said to have been irretrievably lost; the fact that a truth has been once recognized, or partially recognized, and subsequently disregarded proves nothing against it. It only proves that the majority of people have been so blinded by prejudice that they have failed to see it. The world to-day is surfeited with new ideas and improved propositions, and in dealing with them, as scientific men, we can adopt no better rule than that proposed by the great preacher of the primitive church: "Prove all things; hold fast that which is good."

A CASE OF CONGENITAL HYPERTROPHY OF THE ARM AND HAND.

By JOHN A. PRINCE, M.D.,

SPRINGFIELD, ILL.

The following case came under my observation for the first time in September of last year:

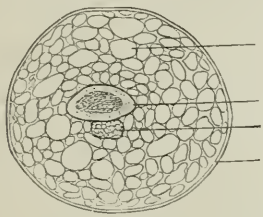
Elsie D——, aged four months, a well-developed and vigorous child. The right arm in its entirety, with the exception of the middle, ring, and little fingers, was very much enlarged, and from the parent's statement, had existed so from birth. The mother and father of the child,

aged respectively thirty and thirty-five years, as well as two other children of three and five years, were in the best of health, and presented no deformity of any kind. Besides the hypertrophy there was present a bifurcation of the index-finger about the middle of the second phalanx, as well as a web between the thumb and index-finger. The skin over the hand and arm was soft, and did not differ in appearance from the skin on other parts of the body. There was no pitting on pressure, but the tissues had an elastic feel.

As well as could be learned from this examination, the hypertrophy was general, including skin, cellular tissues, and bone. The growth of the thumb and index-finger was greatly out of proportion to the rest of the arm, and they resembled clubs more than fingers. It was extremely doubtful whether they would ever be of use, but nothing

was done at this time save the separation of the web to free the thumb, and the parents were advised to return with the child at some future time. Through neglect, a photograph and measurements were not secured at this time.

On September 3d, of this year, I amputated the bifurcated index-finger, and removed a large amount of cellu-



Section of Index-finger, Natural Size.

lar tissue from about the thumb, hoping to be able to save this member and make a useful hand.

During the year that elapsed since I first saw the child the growth of the healthy side has, if anything, gained upon the affected one, though the difference is but slight. The child is very strong and vigorous, as may be seen by the accompanying photograph. The skin is still soft and flexible, and presents none of the characteristics of elephantiasis.

A section of the amputated index-finger, at about the middle of the first phalanx, is here shown, natural size. The hypertrophy is seen to be principally confined to the cellular tissue, though the bone and skin are also to some extent involved in the process. The amount of muscular tissue seemed to be decreased.

The following are the measurements :

Normal Arm.	*Hypertrophied Arm.*
Length, apex of shoulder to the end of index-finger. 12½ inches.	Length, apex of shoulder to the end of index-finger. 17¼ inches.
Circumference of arm at the middle .....7 inches.	Circumference of arm at the middle .....9 inches.
Circumference of fore-arm at the middle.....3¾ inches.	Circumference of fore arm at the middle.....7 inches.
Circumference of thumb at the base ....2¼ inches.	Circumference of thumb at the base ....6 inches.
	Diameter of index-finger at the middle of first phalanx, 1½ inch.

These measurements show a difference of four and three-quarter inches in the length of the normal and the hypertrophied arm. Though comparative measurements of the length of the arm, fore-arm, and hand were not taken, inspection showed that the increase in length is principally in the hand, and nearly two inches of it may be ascribed to the index-finger.

Some difference of opinion exists as to the etiology of this strange disease, it being claimed by some to be of nervous origin, while others, among them Cohnheim, maintain that the beginning is in the embryonic tissues.

On page 210, vol. vii., of the "Annals of Surgery," is an extract from an article by Paul Wagner, of Leipzig, translated by Henry Koplik, of New York, in which mention is made of ten cases in which the hypertrophy involved the whole of one side of the body. Further mention is made, by the same author, of forty-six cases of partial hypertrophy collected by Wittelshöfer, including three of Billroth.

On page 27, vol. i., of the "Transactions of the American Orthopedic Association," is the report of a case of hypertrophy of one lower extremity, by G. N. Packard, M.D., of Hartford. This case resembles elephantiasis, however, in its being caused, as is stated in the report, by congenital occlusion of the lymphatics.

More extended investigation would undoubtedly unearth many more reported cases, but opportunity for such research has been lacking.

PARANOIA: A STUDY OF SOME OF THE MORE PROMINENT TYPES, WITH CONTRIBUTION OF THREE CASES.

By WILLIAM P. SPRATLING, M.D.,

FIRST ASSISTANT PHYSICIAN NEW JERSEY STATE ASYLUM FOR INSANE, MORRIS PLAINS; MEMBER OF THE NEW YORK MEDICO-LEGAL SOCIETY.

In all the domain of morbid psychology there is scarcely a disease whose range of morbid psychic manifestations is so boundless, and at the same time so interesting to the student of diseases of the mind, as paranoia. Much liberality of meaning is essentially bestowed upon the classical definition of paranoia when its practical application is made to morbid mental symptoms classed under that name. We cannot consistently accept its strict etymological meaning and yet allow to remain grouped under this meaning the wide range of abnormal mental displays we are accustomed to meet with in this affection.

Observing the Greek origin of paranoia from *πάρα*, near to, at the side, across; and *νοέω*, to think, to be wise, we find much in it to constitute a basic description of some of the types of paranoia, while for other types, equally as well marked, it has less fitting application. While the fact may seem somewhat singular, it nevertheless remains as one well established, that in all the vast category of degenerative intellectualities, embraced in nearly every form of mental disease, we can find scarcely a symptom whose counterpart does not at some time exist in paranoia. The subjects of this form of mental alienation, it matters little what the type may be, are subject to the same cycles that fix themselves upon other forms of mental disorder. Symptomatic alterations appearing during the course of this form of insanity are not so specialized or distinct as we find them at more or less regular intervals in other psychoses. Still, in paranoia, of whatever type, we can see the varying conditions of morbid mental action appear and disappear with much regularity. A paranoiac of the ambitious type, full of expansive ideas and buoyed with hopes of fame and good fortune, will, as a cycle completes its course, feel these erstwhile living, dominating ideas recede from the field of his mental action, and be replaced by feelings far less conducive to his personal comfort and happiness. These periods of depression do not last long. The mind again becomes actively engaged in its apparently tireless work of creating alluring projects, and vivid, improbable conceptions, some of which may terminate in worthless realities. Later on a case will be described that very aptly illustrates this especial type. We find again, in that form of paranoia in which the subject judges himself to be the object of some form of persecution, much that is common, symptomatically speaking, to melancholia. This is more noticeably true, inasmuch as in each case the sufferer feels himself to be an object of persecution. The spirit in which these chimerical persecutions are received is widely different. The subjects of assumed persecutions in paranoia are aggressive, outspoken, and resentful in proportion to the extent of falsely conceived injury done them. They desire to be revenged, and oftentimes, through personal endeavors, seek to accomplish such desires. Delusions of persecution in melancholia have back of them no such elements as these. In Dr. Noyes's translation of Segla's article that appeared in the *Journal of Nervous and Mental Diseases* in March, 1888, entitled "Paranoia, Systemized Delusions, and Mental Degenerations: An Historical and Critical Review," the author says: "In fact, paranoia is a morbid constitutional form, and the delusion is only a symptom. Moreover, it is not absolutely specific, and may be found in other psychopathic forms without distinct psychological characteristics; but in these cases it is independent of the psychic constitution, and may arise under the influence of an incidental somatic cause." This statement is clear, and doubtless worthy of acceptation, so long as it does not tend to establish too great a difference

between "somatic causes" and causes we might be led to believe lie solely within the psychic constitution. Modern psychology would unhesitatingly interdict this. The boundary line between psychopathic symptoms that spring from somatic causes and those that arise purely from out the psychic constitution is extremely narrow, if, indeed, we can ever positively distinguish between them. It is easy to understand how the presence of a proper somatic cause may give rise to certain mental symptoms we designate as paranoia. Sooner or later, however, the appreciable activity of such causes may cease, and it is after the subsidence of these, the mental symptoms continuing, that we assume the psychic constitution to be responsible for the abnormal display of mental action. There has been some change in the organic base of this. When we have searched all through the list of causes capable of creating morbid mental symptoms, for the special one that gives rise to the mental features under consideration, and find it not among these, then we naturally assume the cause to lie within the psychic constitution. Indeed, this may be at all times its only proper place. Somatic causes of the most productive nature do not, we believe, at any time constitute more than incidental exciting ones, which would be harmless, were it not for the fact that "beyond the Alps there is an Italy;" beyond that in the body, which is purely material, and yet inseparable from it, there is mind. The impressionability of the higher organic elements differ in different individuals. Different psychological stimuli affect different temperaments in unlike ways. In the subjects of paranoia there seems to be a highly specialized tendency to ever put the Ego forward. It enters largely into all their distorted conceptions. It forms the basis of delusions of persecution, and it is strikingly prominent in the ambitious type, where the individual is controlled by kindlier views and conceptions of his surroundings. Those who may become the victims of that type of insanity do not, prior to their trouble, lean in a noticeable degree toward the Ego. Their attitude is most likely to be in an opposite direction—self sacrificing, interested in the welfare of others, and totally devoid of any egotistic or selfish motives. In other cases where the Ego is acquired the individual may have been in most humble circumstances, and never in a position, before the degenerative taint established itself, to speak laudatory of his acquirements.

Of the three cases I have to describe, two are of the ambitious, while the third is of the persecutory type. Of the latter I shall speak first

Case I. is that of J. S. R——, a man, aged fifty-two, married, a native of Pennsylvania, and a Presbyterian minister by occupation. An inquiry into his ancestral history shows no insanity. The family, on both sides, however, is credited with having possessed considerable nervous excitability. As a child the patient had no mental or physical peculiarities or defects. During his college life he was industrious in his habits and an excellent student. He possessed in a marked degree an aptitude for the higher mathematics, securing the honors of his class in these branches. It is interesting to note his fondness for mathematics, for later on we will see how his knowledge of this branch permeates, and is even made use of, in his morbid mental processes. As he grew into adult life he became "morbidly excitable" when mentally overworked, which, owing to his great ambition, was frequently the case. His education had been very liberal. He acquired a high degree of proficiency in the dead languages, including Greek, Latin, and Hebrew, and also fairly mastered German, Italian, and Chinese. At one time, while a resident of the Chinese Empire, he edited a secular paper in the native language. He first went to China in 1868 where he worked faithfully and constantly as an evangelist for four years, when he returned to America. Two years later he went back to his mission work in the East, where he resumed his former labors until June, 1878. Then it was, when his mental powers shone brightest, and his indomitable energies most responsive to the great work he was pursuing, he fell a victim to the mental malady that withered his brilliant intellect, warped, and well nigh destroyed his keen perceptive powers and good judgment, and robbed him of his noble ambitions. A brother of the patient, writing about the cause of his illness soon after it began, says: "Mental strain, probably the greatest of his life, existed at a time when he got overheated while on a short excursion, and all the symptoms of mental disease developed as if by explosion." A period of maniacal excitement followed the outbreak of his trouble, and shortly afterward he was brought back to America, and in October, 1878, was placed in this asylum. The first note of his case, made October 4, 1878, was: "First positive symptoms occurred on 8th or 9th of June last. Became very much exeited; was taken to a hospital, where it was necessary to restrain him. He has been for a year or two quite suspicious of the Catholics in China. Thought they were trying to stab him; thought the doctor in the hospital was persecuting him." Six months after his admission here he became perfectly tranquil and well-behaved. After remaining in this condition for three months, he was allowed to visit his family in an adjoining State, but was shortly afterward returned to the asylum because "he suspected a shopkeeper in the village of improper conduct toward his wife, and trouble followed." Nothing of interest, save the occasional cropping out of delusions of persecution, occurred during the next three years. At the end of that time distinct hallucinations of sight and hearing appeared. The appearance of these augmented his delusions. September, 1884, a note is made to the effect that "mentally he is capable of making astronomical calculations and criticising the observations of others. Has also given much attention to the various meanings of Latin and Greek roots. Is fussy and grasping, suspicious, jealous, and envious. His numerous delusions continue prominent." From that time up to the present no substantial change has been manifested in his mental condition. His life is dominated by manifold delusions of persecutions. At irregular intervals these delusions seem to inhabit the background of his thoughts, and are not subjected to involuntary expression, but these remissions are short. He remains closely in his room all the while. Up to a few days ago he had not been out of the building for two years. Each morning in his room he selects a text, and from it preaches an orthodox sermon. These sermons call forth his strongest reasoning and argumentative powers, and constitute a rehearsal of his efforts in this field fifteen years ago. After the sermon he will devote an hour or more to astronomy and the higher mathematics, covering bits of paper with geometrical figures and algebraic problems. Then comes Latin, Italian, Chinese, and Greek. When through with his books he places every one in just such a position and place, and suffers no change to be made in them. He will cease any form of occupation to tell you of his persecutions, how a fellow-patient, or attendant, when passing his door, strikes with unnecessary force the hard wood floor with the heel of his shoe, the sound resulting from which "impinges upon the drum" of his ear.

Oftentimes he will enter upon a philosophical dissertation on the propagation of sounds, when explaining his persecutions from this source. These sounds strike different parts of his body. To use his expression, he is sometimes "whacked" in the eye, on the eyelid, or on the temples by them. For three or four successive seasons a robin has built its nest in a tree a short distance from his window. He was constantly importuning that the bird be killed, since it took delight in "rasping his nerves with its twitterings." Following is a letter written by him as a complaint against a cripple fellow-patient who is forced to use a crutch. It is reproduced here to show how untenable and absurd are the grounds of his delusions, and to give a more direct impression of his ability as a ready and polished writer:

"*To the Authorities of the New Jersey State Asylum at Morris Plains:*

"GENTLEMEN: This is to depone that one D——, a patient of this asylum, is permitted, and has been permitted for the past four years (*circa*), to post himself *ad libitum* from morning till evening, when the weather is not stormy nor inclement, in the rear ward of the second building on the north side, and there to spend his entire time in exercising a prurient and offensive animosity. In a self-arrogated judicial capacity he inflicts with the end of his crutch, in a *quasi* 'jeu de béquilles,' delivered in a semi-sportive spirit, impacts upon the temples and tympana of deponent, and of other pious fellows, with a view to damaging them both physically and morally. The deponent, therefore, in the name and behalf of the sufferers at the crutch of said D——, and for the sake of religious and moral interest that is at stake, does hereby respectfully petition the asylum authorities that said D—— be definitely deprived of all opportunity and power to prosecute his injurious, unjust, and outrageous endeavors any further, by relegating him to a back ward, where he will find it impossible to hurt valuable health and curtail precious lives.

"Very respectfully and sincerely,

"J. S. R.

"September 8, 1890."

The complaint in this instance is based upon sounds caused by the cripple man's crutch striking the stone steps as he daily goes out into the courtyard. These instances are sufficient to show the general character of his delusions. He learns nothing modern; reads no daily papers, journals, or periodicals, save perhaps a mission pamphlet or an Italian newspaper occasionally. Like Lot's wife, he is ever looking backward. His conversations all bear upon the past. He will talk for hours on reminiscences bearing upon his life while a missionary in China, and of his college days; but of his family, home, and friends of the present he rarely speaks. His personal appearance is striking. A large, finely shaped head, full blue eyes that faithfully indicate the storm or calm within, and an agreeable suavity of manner that he seldom puts aside. The study of this man's once brilliant, but now maimed and withered, mind is not more fascinating than it is strange. To understand how such insignificant and delusive ideas dominate a mind so fraught with magnanimous impulses, with such breadth and liberality of highly intelligent views, is for us too great a task. It is, without doubt, a true degeneration, and the prognosis, as regards an ultimate recovery, is unfavorable. We do not believe that he will pass into dementia prematurely, if he retains his energies and continues to exercise his mental faculties as he does to-day.

CASE II. is that of A. F. D——, male, fifty-four years of age, unmarried, and a native of New York. His parents were both natives of Germany. His education in early life was good, comprising a complete academic course. By reason partly of his family's affluence, and partly on account of some early manifestation of mental obliquity, he never had any definite occupation. This obliquity first appeared when he was twenty years of age, and it was thought to have arisen in consequence of "disappointed affections." This supposed cause, however influential it may have been, was doubtless largely reinforced by a hereditary taint that was present in two of his ancestors on his mother's side. He resembles his mother. In disposition he was always gentle, but easily excited, a tendency that has undergone rapid development. It was stated at the time of his admission that he had an attack of insanity in Germany, in 1858, when it was necessary to restrain him. The duration of this attack is not given. It seems, however, that he had not fully recovered from it twenty years later, when the more pronounced symptoms that characterize the present attack made their appearance. During the entire period between the first and second attacks he was never free from "hallucinations and illusions." On his admission here in the fall of 1881, he was regarded as a "monomaniac on the subject of inventions," and his subsequent course up to the present time has only served to emphasize the correctness of this view. There is nothing at present eccentric, remarkable, or even strange in his general conduct or actions, save his massive ideas regarding inventions, and the abnormal enthusiasm that is engendered whenever the subject of inventions is discussed in his presence. The very mention of some new invention lends a brilliant lustre to his eye, puts his whole body in a tremor of excitement, and visibly stimulates his entire organism into a wonderful, restless activity. He speaks rapidly, punctuating and emphasizing with gestures what he says. A few compliments upon his work, or to tell him of the possibilities of his conceptions, will increase his enthusiasm, until his haste to explain this or that particular feature of an invention will make him unintelligible; sentences and even words will be but half-spoken in his haste to express them. At times the process of ideation is so forcible and rapid that he cannot bring into sufficiently rapid action his vocal powers to express the ideas created. For some seconds a rapid, incessant movement of the lips, with an occasional semi-intelligible word, is all there is to denote mental activity. This extravagant enthusiasm is only shown when he has sufficiently studied the problems involved in a new invention to determine that it is, to him at least, a safe and feasible project, "with millions in it." When lost in abstract thought over some problem that pertains to the evolution of his invention he is apt to be in a frame of mind less sanguine, and his usual display of good nature is lacking. At such times he is mildly depressed, easily irritated, full of fault-finding, and does not care to be disturbed. During these times he suffers from hallucinations of hearing, which misinterpreted sounds his inventive genius is always ready to correct or modify. In a toilet-room on the ward of which he is an occupant a small stream of water flows constantly, and the noise made by this slight overflow, which he describes as a "system of leaks and driblets," is a constant source of annoyance to him when in this depressed condition. He has invented innumerable contrivances to correct this annoyance, one plan being the erection of a separate four-story building, a short distance from the main ward, in which shall be placed all toilet arrangements. Scarcely a fortnight for the past five years has passed during which period he has not invented something, that, to use his own words, "will bring great good to the world, and give a fortune to all who take stock in it." He will not hesitate to sell for a fraction of a dollar stock in any of his inventions, which stock he may consider worth ten thousand dollars or more. Among his inventions of late may be mentioned a "deck-seat life-preserver." This life preserver is unique, and deserves a short description. It is made of two tin cylinders, about four feet long each, eight inches in diameter, pointed at one end, and fastened side by side. Upon them is placed a plush covered, freely movable seat, so that in case a rough sea should upset the cylinders, the seat could be easily transferred to the uppermost side. Other inventions are: a fire escape; a cambric-covered fever pillow, that is supposed to absorb any excess of heat from the head; an alphabet of raised letters on wood for the blind; numerous in-door games for children; a means of carrying off water from the Ohio River in time of freshets; a machine for separating wheat from chaff; a hygienic tower ten thousand feet high; numerous carved wood receptacles for holding small oval clocks; a car coupler, the operation of which is a puzzle to all save the inventor; a sliding easel that elevates or lowers a picture to suit the artist; and an apparatus for executing criminals. The recent electrocution in New York State bestirred him to produce the latter. His invention provides that the person shall be killed by having a sharp steel pin driven into the back of the neck, so as to strike the medulla oblongata. It is

impossible to give the names of all his inventions, for they are legion. His mind is never free from such ideas, nor does he ever lose courage or faith in himself. His inventions, he says, "are not chimerical, but original, and, being based upon organic laws, are millionaric." He is allowed the freedom of the grounds, and spends most of his time in the carpenter shop, making models of his inventions. His health is remarkably good; his bodily functions are all normal; and his life is quietly spent, save the agitation caused by his active inventive ideas.

Case III. is likewise one of the ambitious type, and, while differing in its elementary character, and not so prominently marked as the one just related, it possesses characteristic symptoms. It is that of W. G. B——, an unmarried male, thirty-three years of age, and a native of New York State. His ancestral history shows no insanity. As a child he had no physical defects or marked mental peculiarities; his mind at times evincing some weakness. He acquired a fairly good education, but his comprehensive powers were limited. In disposition he was amiable, kind-hearted, and mild. He worked as an ordinary laborer up to the age of thirty. Most of his spare time was spent in reading works of fiction, with a decided preference for certain authors. He was brought here in May, 1888, because "he gave up his work and desired to go into the dry goods business, although he had not a penny in the world." About the same time he acquired a belief that a wealthy family in Philadelphia was desirous of adopting him and preparing him for the Methodist ministry. It was afterward learned that his idea for desiring to go into the dry-goods business was that he "wished to make money with which to improve and fit himself to preach the Gospel." Soon after he was received here he began to elaborate his interpretation of various passages in the Bible by means of drawings that were not without some merit. He soon covered the walls of his room with odd and fantastic pictures, each one intended to be an interpretation of some annexed phrase or quotation from the Bible. His talent for drawing was not manifested until he became imbued with the desire to be an exponent of the Gospel. At one time he had a number of pictures fixed upon the wall over his bed that he intended should represent the convergence of the entire American commonwealth toward the Supreme Being. A large map of North America, roughly sketched and outlined by himself, constituted the base of the group of pictures. Just above this he placed the picture of the American eagle, life size, done by himself. Above this, the figures of two cherubs appeared to be floating in clouds. This was in turn surmounted by the figure of the Saviour, over which appeared a picture of the sun as a crowning glory. The arrangement of these pictures illustrates the bent of his ideas. His mind is inherently weak. While his demeanor is usually quiet and gentlemanly, his speech low and dignified, he is subject at times to a noticeable departure from this condition. Being required to perform some light labor in the ward, he sometimes breaks out into fits of rebellious passion, but they soon subside. His life appears to be governed by his one ambition. His confinement never seems to grow irksome to him. For two and a half years these morbid ideas have been grafted upon a mind inherently weak. We can hardly hope that they will ever be eradicated.

There is one point of difference peculiar to each of these cases. The mental instability in the first case was wholly acquired, being fixed upon a brilliant mind, free from hereditary taint. In the second case the hereditary taint was present, being indirectly transmitted; while the third possessed a mind congenitally weak. In the first case how can we account for the fact of the patient's inability to learn anything new? It would seem that the impressionability of the higher nerve-cells for new impressions has been destroyed, or the impressions that were made upon the cells prior to the disruption of their normal functionating life have become so intensified and fixed as to inhibit anything that is new. If it be that the impressionability of the nerve-cells has been destroyed, the destruction has been so actual and complete as to transcend the point where the damage may be subject to physiological repair.

THE NORMAL REFRACTION OF THE EYE.

By FRANK VAN FLEET, M.D.,

ASSISTANT SURGEON MANHATTAN EYE AND EAR HOSPITAL; LECTURER ON DISEASES OF THE EYE, NEW YORK POST-GRADUATE MEDICAL SCHOOL.

The student of ophthalmology finds very many questions to interest him to-day, and they are all the more interesting because the answers given by different observers are so much at variance. The teacher, therefore, is often at his wit's end to find terse and concise answers which will satisfy the beginner as these conflicting statements are met with and bother and harass his inquiring mind.

Hardly can it be the duty of any man to set straight these crooked and devious ways, but it is the privilege of any one who cares to take the trouble to set forth his own opinions and try to untangle the ravel.

Man is essentially a builder of ideals. We try to set up the perfect image and make all else conform to it. And in many instances facts are diverted and twisted until little semblance of the original remains. We get in our mind's eye, so to speak, the road we see mapped out and travel straight ahead, each in his own way, often never looking for the rich fruit that hangs by the wayside.

It is said that an eminent Egyptologist, searching for facts, modified the results he had obtained from Egyptian monuments, in order that his chronology might not interfere with the received date of the deluge of Noah (Andrew D. White, *Popular Science Monthly*, June, 1890).

Man is a product of nature, and as such subject to nature's laws. Nature does not build rigid angles but rather rounded lines, and so the ideal in nature is rarely found; art is proverbially more perfect.

And so man in his study of the eye has set up the ideal which he calls the normal. Art has constructed an eye which we call the camera obscura, which may be made optically perfect. In many respects a similarity exists between this device of man, this work of art, and the human eye which is the work of nature.

When the camera is in position, its arrangements perfect as far as its internal parts are concerned, all that remains for the photographer to do is to get his focus. His camera, erected on its tripod, must be moved away from or nearer to the object, as the case may be. If this eye of ours was built entirely on the same plan the same methods might suffice. As we have the camera with its lens and its blackened box set on a moving machine, we might get our focus by stepping backward or forward. But nature has been kinder, and, instead of compelling us constantly to resort to this forward and backward movement, has supplied us with muscular abilities which obviates the necessity, and here the simile between nature and art ceases.

Man has set this optical machine as the model, and as the focus of the lens in the camera coincides with the sensitive plate in the back of the box, so it is said that the normal eye has a focus which exactly coincides with the sensitive plate or retina, and this while the eye is in a state of absolute rest. Therefore, if the refractive power be the same, all eyes refractively normal must have a certain definite length between the sensitive retinal plate and the anterior surface, the cornea.

This eye is emmetropic, and is accepted as the ideal eye, and while the bold statement is not made in medical books devoted to ophthalmology that this is the normal eye, it is generally understood to be the case.

Donders in his work makes the positive statement, however, that the emmetropic eye is the normal eye. And so we are not surprised that the statement is made that ninety per cent. of all human eyes are abnormal. This, then, is the keynote, ninety per cent. of all human eyes are

ametropic. This is certainly a remarkable statement, and yet if we accept the statement that the normal eye is the emmetropic, and if the facts are as stated that the emmetropic eye is one which in a state of absolute rest focuses parallel rays on the retina, then we are forced to admit its truth. We are then brought face to face with the alternative, namely, either man is an anomaly in so far as his eye is concerned, or else the standard is incorrect.

Which is the more likely? In all but this nature has endowed man with organs which in a state of health perform their functions normally and are therefore constructed normally. At least this would be the natural deduction. But with the eye, although the vast majority perform their duties normally and are capable of all things for which they were intended, yet—wonderful paradox!—ninety per cent. of them are constructed abnormally. And how do we prove this? By looking through the books devoted to this subject we find, as for example in Landolt, pages devoted to the proving of this remarkable fact. We prove it with a mass of figures that have been aptly called by Heyl mathematical fiction.

What are the facts? We are taught to recognize three kinds of eyes, namely, the emmetropic, the hypermetropic, and the myopic. We recognize still another refractive condition, namely, astigmatism; but while much has been said and written about this condition, and while it causes most of the trouble of which so much has been done in the way of discussion, and which is of all troubles perhaps the most amenable to treatment, it is not within the scope of this article to enter into its consideration. So we will lay it tenderly aside for some future time and concern ourselves only with the three grand divisions above mentioned.

For the sake of those who may not be conversant with the meaning of these three terms, and there are such, we will give an explanation of what we understand by the names emmetropia, hypermetropia, and myopia before proceeding further.

By the term emmetropia we mean that the dioptric system with the eye at rest focuses parallel rays of light on the retina—in a state of rest meaning that the accommodative power is absolutely relaxed.

Hypermetropia means that the eye in its antero-posterior axis is too short, and that parallel rays are focused behind the retina.

Myopia means that the same axis is too long, and that the focus is in front of the retina.

And so we have the hypermetropic eye on the one hand, being too short; the myopic on the other, too long, and the emmetropic, the happy medium, and neither too long nor too short, but just the proper length. Now this implies that the strength of the dioptric system is the same, the eye being in a state of rest. Of course an eye might be of less diameter antero-posteriorly, but if its refractive strength was greater than usual in a state of rest it would still be emmetropic; but as writers of text-books give the length of the emmetropic eye as being 22.824 mm., the fact that the lens might be a little more or a little less convex is not considered. And so all eyes less than this are hypermetropic; all more, myopic. The emmetropic eye, therefore, at rest is focused for distance, and for near sight calls into play its accommodative power and still maintains its focus on the retina.

The hypermetropic eye has no focus; for rays from infinity the eye is too short, and as the object viewed approaches the focus is brought still farther back, so that the only way in which this eye can see at all is by constantly making use of its accommodative power, which it does.

The myopic, on the other hand, has a positive point of distinct vision, but it is situated very near. As there is no power of negative accommodation, this eye cannot, by any effort of its own, see clearly distant objects. As this eye is too long, objects must be brought closer, so that the rays which enter the eye may be divergent. So we see that the range of vision in this eye must be very limited. Accommodative power is of little value here, in fact only increases the difficulty, and naturally in these cases we find the muscles concerned in this action illy developed. Quite the reverse from the hypermetropic eye, in which, as would naturally be expected, the muscular apparatus reaches its greatest development.

And yet this weak myopic eye, with its one point of distinct vision, its illy developed muscular apparatus and usual train of unhappy symptoms, is the eye that Landolt would have us believe is the eye of the future—the eye which marks the type of the highest order of development. We, the proud and haughty genus homo, whose mental and physical being is constantly growing and expanding, who in the rapid stride of civilization are giants alongside our ancestors, must in the end have myopic eyes. Alas, the reward is inadequate.

Now, in order that the emmetropic eye can distinctly see objects situated at infinity, it is necessary that the accommodative power be absolutely relaxed. Because if ever so small a part of accommodation be used, the focus would be brought in front of the retina, and instead of a point, circles of diffusion would be formed and the object be blurred. Can the accommodation be absolutely relaxed?

According to Donders absolute relaxation of the accommodation can and does take place, and in describing the action of atropia says there occurs diminution and soon *total* loss of accommodation. And yet at another time he makes the statement, as I understand it, that it is customary for the emmetropic eye under full atropia mydriasis to accept a + glass of scarcely $\frac{1}{60}$. Again, in speaking of the paralysis of the motor oculi nerve he says it is rarely complete, some, though slight, accommodation still remains.

Donders, in speaking of the connection between the contraction of the pupil and accommodative action, says that there is a direct relation between the two; this we accept to-day as without doubt the case. And he says that Listing observes that contraction of the pupil takes place contemporaneously with the will. Again he says that disturbance of accommodation is most distinctly revealed by deviation of the iritic movements.

Now, the action of the iris and ciliary muscle are controlled by the same source of nervous supply, namely, fibres derived from the lenticular ganglion, which receives its motor force from the motor oculi. True, it is said that stimulation of one point of the origin of this nerve will produce contraction of the iris, of another, contraction of the ciliary muscle. But the statement is not made, as far as I know, that the will can be so directed as to cause contraction of the one independent of the other.

Some investigators have claimed to have discovered fibres of dilatation in the iris, as Raettera and Picque, who believe in the active nature of dilatation governed by the sympathetics. Chauveau, Debrerre, and others, however, believe that dilatation of the pupil corresponds to a state of rest. It is not even definitely settled that accommodation is entirely due to contraction of the ciliary muscle directly and alone, as Coccius thinks that the tensor choroideæ acts directly on the posterior surface of the lens and thereby changes its form. This being the case it antagonizes in its action the rest of the muscle. Nor is it certain either that the lens is the only part of the eye concerned in its accommodative power, as we find in Donders the statement that Thomas Young, von Graefe, and Jaeger think that some accommodative power remains in the eye after removal of the lens.

Donders himself thinks that in the aphakial eye not the slightest accommodative power remains. But he qualifies this by saying that if any remain it is less than $\frac{1}{300}$, which may be considered as nothing. Be that as it may, certainly if any remain, be it ever so small, it proves the existence of a power situate in some other part. In Sajous's *Annual* of 1889 we find this quotation from Heyl: "When one is walking along the street with the mind absorbed in thought, the macula of each eye is

pointing at one point in space. In this there is no conscious exercise of the will." This is in accordance with my own observation. In this condition we may see objects before and around us but we do not recognize them. But when we desire to gain distinct vision we make an effort. We bring to bear on the object our visual lines, and there is an exhibition of will. Now, with this exhibition of will there occurs contraction of the pupil. Who shall say that there is not some accommodative power brought out to play at the same instant? Inasmuch as Donders says that the emmetropic eye under full atropine paralysis will accept a weak convex glass, it is probably true that there is. Obviously, then, this eye is not emmetropic, or if it be emmetropic now, it wasn't before. If it focuses now, under influence of the will, parallel rays on the retina, the same rays in the relaxed condition of the eye would have been focused behind the retina. This eye, therefore, must be hypermetropic. And so I make the statement, from the foregoing analysis, that the eye which under the influence of the will, which is a necessary accompaniment to distinct vision, focuses parallel rays on the retina must be hypermetropic, and that all other eyes are myopic. Arminski says that the hypermetropic eye is the normal refractive condition in the uncivilized man. But he might have included in this statement the whole human race, civilized and uncivilized.

The hypermetropic eye, too, is the eye which abounds in nature. Jaeger made the statement that the eye at birth was myopic. Ely was perhaps the first to disprove this, although at almost the same time, or shortly after, many other observers placed their proof in the field that the eye at birth is hypermetropic.

Ely examined 111 children, only six of whom were over two months old. He made satisfactory examinations in 90 children and 154 eyes. His method was as follows: He first paralyzed his own accommodation with atropia. He did the same to the eyes of the children, he also gave each child an anodyne in the form of paregoric, which, would seem a very necessary proceeding. Then with the aid of a Loring ophthalmoscope and an assistant who held the child's eye open, he conducted his observations. He found hypermetropia in seventy-two per cent., myopia in eleven per cent., and emmetropia in seventeen per cent.

Jaeger used no atropia, which may account for his error, as Ely found in 49 eyes where he didn't use atropia a much higher percentage of myopia. But in the cases in which he did use atropia, it is quite likely, as atropia does not entirely relax the accommodation, that all those put down as emmetropic were really hypermetropic, and we can safely say that hypermetropia exists in at least ninety per cent. of all human eyes at birth.

Nor are we compelled to depend on Ely's finding alone. Risley in 2,422 eyes found hypermetropia in seventy-four per cent., myopia in eleven per cent., and emmetropia in thirteen per cent. in school children ranging from eight to seventeen years of age. And if the emmetropic eye is really hypermetropic, then eighty-seven per cent. of these children were hypermetropic.

Hansen, in 1884, found 94.4 per cent. hypermetropic in 805 children. Many others have likewise published the same results.

Hypermetropia, therefore, is the normal condition and the only condition which is consistent with clear and distinct distant vision. That the majority of the human race have this is, I think, true without doubt.

Dr. Herndon, Surgeon United States Navy at the recruiting office in this city, informs me that less than five per cent. of all applicants at his office have vision less than $\frac{xx}{20}$. And so, as most of the human race have distinct distant vision, and as such vision can only be obtained by the hypermetropic eye, and as it was doubtless intended that this was the form of eye which should be part of the human race, we feel justified in saying that the hypermetropic eye is the normal eye, and while it might hardly be true to put it at ninety per cent., it is at least safe to say that the large majority of human eyes are refractively normal.

Leaving out of this discussion, as I said above, the presence of astigmatism, we have, then, two grand divisions into which we ought to divide the refractive condition of the eye, namely, the hypermetropic or the normal, the myopic or the abnormal.

Emmetropia, in the ordinary acceptance, does not exist, except as the beginning of myopia.

As Arminski says, myopia is the product of civilization developed in the struggle for existence. Emmetropia is only a stage of transition to myopia.

Progress of Medical Science.

Massage of the Prostate.—Dr. Eberman presents the following conclusions as to the value of massage in prostatic disease: 1. It can be advised (*a*) at the decline of an acute parenchymatous inflammation where there remains difficulty in urination, the gland being still slightly swollen and but little painful; (*b*) when the acute or chronic inflammation terminates in abscess, the massage having for its object the evacuation of the pus and the resorption of the engorgement still present; (*c*) in cases of chronic parenchymatous inflammation with swelling; (*d*) in soft hypertrophy with uniform consistence of the gland. 2. Partial hard myomatous hypertrophy of the gland is not susceptible of massage; however, the massage in this case does no harm, and it can be tried, first introducing a pewter bougie into the urethra. Perhaps if the resorption of the tumor is not effected, the urethra, which has been modified by the irregularities of the hypertrophied prostate, may be again restored to proper calibre. The middle lobe of the hypertrophied prostate encroaches upon the cavity of the bladder, and by reason of its situation cannot be subjected to massage.—*Wratch.*

Cure by Operation.—In a paper by Dr. J. W. White, of Philadelphia, the interesting question of successful results following operations which are in themselves failures is discussed, and the following conclusions drawn: 1. There are large numbers of cases, of different grades of severity and varying character, which seem to be benefited by operation alone, some of them by almost any operation. 2. These cases include chiefly epilepsy, certain abdominal tumors, and peritoneal effusions and tubercle, though the improvement in the latter is, perhaps, to be explained on general principles. 3. Of the possible factors which, by reason of their constancy, must be considered, anæsthesia seems least likely to have been effective. The other three, viz., psychical influence, relief of tension, and reflex action, may enter in varying degrees into the therapeutics of these cases, and, taken together, serve to render the occurrence of occasional cures less mysterious. 4. The theory of accident or coincidence scarcely explains the facts satisfactorily.—*Annals of Surgery.*

Cystoscopy.—Dr. Wallace recently read a paper before the Medico-Chirurgical Society of Edinburgh, on the value of cystoscopic examinations, based upon an experience of over fifty cases, in which he states that the cystoscope is of the greatest value, not only in obscure bladder disease, but in renal affections as well; but he does not deem it necessary to use the instrument in all genito-urinary diseases. Fourteen tumors were included in his cases, twelve of which were operated. Five were papillomata, one a leio-myoma, and eight were villous cancers. In four of these cases, as indicated by the histories, the diagnostic value of the cystoscope is vividly exemplified. Some of the points to bear in mind in using the instrument, are: 1. To take precautions against chill, as in other examinations of the bladder. 2. The urethra must have a calibre sufficient not merely to allow the introduction of the instrument, but also to admit of free move-

ment of the instrument within the bladder. 3. It is imperative that the bladder should contain at least six ounces of clear fluid. Local or general anæsthesia if pain is occasioned. 4. The examination must be methodically and carefully made, and the whole interior of the bladder thoroughly investigated. The "anterior" instrument has the greater sphere of usefulness; with it all parts except that opposite the opening of the urethra can be examined. 5. As most affections are situated in the inferior third, it is to this part that particular attention should be directed, though ulceration of the roof of the bladder may occur. 6. When an abnormality has been discovered, the beak of the instrument must be moved into different positions to determine exactly what is seen.—*Edinburgh Medical Journal.*

The Diagnosis and Treatment of Puerperal Eclampsia.—Dr. Löhlein, of Giessen, who has made a statistical inquiry from all German clinics for the years 1888–90, inclusive, out of a total of 52,328 labors, found 325 cases of puerperal eclampsia (*The Medical Press*). The disease was most prevalent in the Charité, where it occurred once in 67 cases, and least in Vienna, where the proportion was only one in 328. Of the 325 cases, 63 died of the disease, and 14 others of complications; the mortality was therefore 19.38 per cent. The lowest mortality was in primiparæ attacked after labor (11.6 per cent.), the highest in multiparæ attacked before the birth of the child. Among the 248 who survived, 13 suffered later from psychosis, from which the majority recovered completely, and 82 from persistent renal diseases (11 cases of chronic nephritis); operative interference was called for in 71.1 per cent. of the cases; forceps, 108; turning, 19; operation for diminishing the size of the fœtus, 13; artificial induction of labor, 2; Cæsarean section, 7 times, 5 times on the dead mother, 1 on the dying mother, 1 on the living, with a successful result for both mother and child. The latter method of treatment would be in place only when the child was certainly living, but in great danger of being killed, and in which no narcotic stopped the convulsions, and when there was no other way of effecting speedy delivery. As regarded medicinal treatment, large doses of morphia deserved the preference.

A New Method of Establishing a Gastric Fistula.—Dr. Witzel, of Bonn, describes a recently devised modification of the technique of gastrostomy, which, it is asserted, will prevent the escape of gastric juice, which in many instances causes so much trouble after this operation. The object of this procedure is to establish a canal, formed by stitching together the free borders of two parallel folds of the exposed wall of the stomach. This canal extends obliquely from the right downward and to the left, where it communicates with a small opening made into the interior of the stomach, and an arrangement is thus established which resembles the lower extremity of the ureter as it passes obliquely through the wall of the bladder. It is necessary, in practising this method, to draw a large extent of the anterior wall of the stomach through the external wound. This, it is stated, can be readily effected, when the stomach is collapsed, by gentle and prolonged traction. Two parallel folds following the above mentioned course are then taken up, the free margins of which are brought together by three or four Lembert sutures, and by numerous ordinary sutures, over a flexible tube of the thickness of a lead pencil, the lower end of which tube is inserted into the small opening made into the stomach, while the upper end is intended to project from the external wound. The canal thus formed, which should be about one and a half inch in length, is left exposed at the bottom of the wound when the stomach is fixed by sutures to the margins of the external incision. This modification does not necessitate any change in the other steps of the operation, and the surgeon can make the external wound according to his usual practice. Witzel exposes the sheath of the rectus by an incision made parallel to, and at a distance of a finger's-breadth from, the margin of the ribs; then, as is done in House's operation, he separates the fibres of this muscle in a vertical direction, and incises the transversalis obliquely from above downward and from the right to the left. The division of the rectus thus crosses the wounds made through the skin and the transversalis. Witzel, who has operated in the manner described on two patients, has had good reason, he states, for being well satisfied with the results, and believes that his expectation of establishing a gastric fistula capable of being effectually closed by valvular action has been fulfilled.—*Centralblatt für Chirurgie.*

Clinical Department.

CLINICAL HISTORY OF THREE CASES OF TYPHOID FEVER.

By S. L. HANNON, M.D.,

WASHINGTON, D. C.

Within the last two years I have met with a number of interesting cases of enteric fever. Of this number I have notes of three typical cases—two survived, the other died from the effects of exposure and the lack of good nursing.

Case I.—Ella H——, aged eighteen. On July 24, 1889, I was called in and found the patient with a high fever (105° F.), frontal headache, tympanitic, tender abdomen, frequent pulse, coated tongue, red on tip and edges, constipation, cough, with bronchial râles. She had been sick for about one week, her nose had bled frequently during the night, she had suffered with disordered digestion and insomnia, and had had two chills, for which she had been taking patent medicine. I gave her ten grains of antipyrine every four hours for the fever, and ordered tepid sponge-baths and a liquid diet of milk and beef-tea. Turpentine stupes were ordered for the pain in abdomen, and glycerine suppositories for the constipation.

After noticing the temperature record for two or three days very closely I found it characteristic of typhoid fever; the nervous symptoms became more and more noticeable, and the patient was rapidly passing into a drowsy and stupid condition, with low muttering delirium, and impaired sight and hearing. About this time diarrhœa came on, which was troublesome, but was kept under control, and I now noticed the rose-colored spots which I could not see before. The nervous symptoms became worse. The girl would scream, pull her hair, toss, and get herself into almost all imaginable shapes. I called Dr. D. K. Shute into consultation, and rather large doses of bromides were ordered, with stimulants. I gave her one-eighth grain of sulphate of morphia at night, hypodermically, which was satisfactory to some extent. This nervous condition lasted, I thought, unusually long, but about the middle of the fourth week I noticed a marked change in favor of recovery. She began to notice her surroundings, sleep better, and take nourishment with more relish, and the pinched and prostrated look about the face was gradually disappearing. She continued to improve very rapidly, gaining in strength, and was almost ready to sit up, but during the absence of the nurse got up and walked about the bare floor to look out of the window. The next day she suffered severe pains in the lumbar region, which was evidently lumbago. A few days later on she became very contrary and melancholy, refusing to obey the orders of the nurse in any particular, and had numerous imaginary pains. At first small doses of morphine were administered, combined with other remedies, for the pain in the back. She would groan all night and at times cry and laugh and complain of the lumbago. I administered one drachm of distilled water, which had the same effect as the morphia, showing to a degree of satisfaction that her pain at this time was imaginary, and that I was contending with a case of pronounced hysteria. She refused to help herself, even so little as to turn over in bed, and would scream if any-

one would attempt to assist her, but when determination and force were used she was moved without pain. She had been in bed now nearly nine weeks and was getting in a bedridden condition. She was taken, by the request of her father, to her home in the country, where she continued to improve and became reconciled to the surroundings she had been used to, which, combined with fresh air and pure spring water, had a good deal to do with her final recovery.

Occasional attacks of melancholia recurred from time to time, but she has now recovered and has the original appearance of a healthy country girl.

Case II.—Anna B——, aged nineteen, colored, had two chills the day previous to calling me in, which was on November 8, 1889. She had then a temperature of 105.5° F., and her nose had been bleeding profusely. On account of the accommodations I tried to get her to go into the hospital, but she instead went to the house of some colored relatives. Her temperature continued high, and the diarrhœa was severe. She was put on antifebrin for the fever and given tepid sponge baths

On November 12th I concluded that I had another case of typhoid which might prove troublesome. This patient, like the first, had the regular typhoid symptoms, and I treated her accordingly, although the surroundings were not the best. The patient, however, did well until the eighteenth day of her sickness, when the diarrhœa became more aggravated, for which I ordered—

℞. Tinct. opii. deod. ..... ʒ ij.
Ol. terebinth. ..... ʒ ss.
Aq. camph. ..... ʒ iss.
Pulv. acaciæ ..... ʒ iss.
M. et Sig.: Teaspoonful every three hours.

The fever was under control. I gave positive orders not to allow the girl to get up for any purpose. My orders were disobeyed. I was called out on the morning of the 28th, at four o'clock, in haste. On arriving I found the patient unconscious, gasping for breath, with a temperature of 92.5° F. The radial pulse was not perceptible. Putting my ear to the chest I could scarcely hear the heart beat. On inquiring what had happened I found that she had been allowed to get up twelve or fifteen times to relieve the bowel, and had had two large hemorrhages from the intestines. The first I did not see, the last I did; it consisted of twelves ounces of black blood. I had no time to lose, for I thought that every breath the poor girl took was the last. I immediately injected several drachms of whiskey into the arm; also administered ergot and sulphate of morphine hypodermically, but could not see that I had benefited her any; yet there was life.

I thought of a case of which I had read where ether had been used to save a life in case of post-partum hemorrhage. I had a bottle in my bag which I carry at night when called out, and at once injected several drachms into the thigh. After having exhausted all the means at hand, I now sat down, and, very much to my surprise, in a few minutes the girl began to breathe better. The radial pulse could be felt, the heart had begun to do its work. I then ordered whiskey every hour, with the following prescription:

℞. Fld. ext. ergot ..... ʒ j.
Liq. ferri. sub. sulph. ..... ʒ iss.
Ol. terebinth. ..... ʒ j.
Pulv. acaciæ ..... ʒ ij.
Aq. camph. ..... q. s. ad ʒ ij.
M. Sig.: Teaspoonful every two hours.

The girl continued to get better, and in two weeks was well enough to sit up. The sequelæ in this case were a cough, marked deafness, and cessation of the menses. The last time I heard from the patient she had greatly improved, and is now enjoying reasonably good health.

Case III.—This case came under my care in the fall of 1890 while at Fort Stevenson, N. Dak., in the Indian service. An Indian girl had been sick for three or four days with high fever. I was called in and found her with a temperature of 104.5° F. She was of a scrofulous diathesis. Several large ulcers and discharging glands were seen about the neck and axilla. I found, as in the two preceding cases, typhoid symptoms, a short, hacking cough, severe pain in the abdomen, epistaxis, diarrhœa, etc. The nervous symptoms set in early, the delirium being of an active and noisy kind, soon becoming violent. I ordered about the same treatment as in No. 1 and No. 2, but there was lack of good nursing. The father of the girl was sent for. On his arrival he proceeded to give the girl massage treatment, a custom among the Indians, rubbing the abdomen and chest vigorously. I happened to call to see my patient just about the time that he was well under way in his treatment, and with some difficulty persuaded him to believe that he would injure his girl. The following night she had two small hemorrhages from the intestines, for which I administered ergot by the mouth. I was laboring under some difficulty as to the nursing. The patient was progressing very nicely, and was, I thought, on a fair way to recovery, when a sudden change in the atmosphere occurred, the mercury falling to ten degrees below zero. I instructed the attendants not to let the room get cold, but my instructions were not obeyed. On going into the room at twelve o'clock at night I found the nurse fast asleep, well wrapped up in Government blankets, while the patient lay in a semi-conscious condition, half-naked and very cold. The cold air was rushing up through the floor, in fact, stealing through every crevice penetrable. I made a fire, wrapped the patient up as comfortably as possible, left orders for her to have whiskey every two hours, alternating with milk, placed her in charge of the nurse, and retired. The next morning I found a change in the patient for the worse. She was breathing with difficulty, and her temperature had fallen below normal. I increased the whiskey and nourishment and had her wrapped in warm blankets. About four hours later I was called in haste and found her suffering with dyspnœa, with large quantities of red, frothy fluid exuding from the mouth and nose, the eyes were congested, and the carotids and temporals were throbbing. I cupped the girl over the chest, used sinapisms and rubefacients, gave her ammonia, aconite, and whiskey every ten or fifteen minutes; used all means that I could think of to save the poor girl's life, but all was in vain. Cyanosis soon set in, the pulse becoming more feeble, the extremities grew cold, and stupor came on, ending in coma and death.

In the first case we notice that the patient was a healthy country girl. The temperature ran high, there was slight diarrhœa, and extreme nervous symptoms were noted, leaving hysterical manifestations as a sequela. In the second case we also have a girl that had always been healthy. We notice high fever in the beginning, and troublesome diarrhœa, intestinal hemorrhage as a complication, and deafness and amenorrhœa as sequelæ. In the third case we had nervous symptoms with intestinal and lung complications. In this case there was a lack of good nursing and proper care. The complication which killed the patient, no doubt, was œdema of the lungs, caused by the exposure.

REPORT OF TWO CASES OF LAPAROTOMY.

By E. M. POND, M.D.,
RUTLAND, VT.

Case I. *Tubal Pregnancy, Rupture of Sac, Recovery.*—Mrs. H——, aged twenty-four, married four years; previous health good, except occasional slight pain in the right side. Menstruation was normal, and she had never been pregnant. October 1, 1890, her normal menstrual period, she had a severe cramp in her bowels, but as it was soon relieved, did not summon a physician. Menstruation did not occur. Two weeks after she was seized

with a violent paroxysm of pain situated in the lower abdomen, and running through the right side and back, terminating in collapse, a subnormal temperature, and a pulse of 120; from which she rallied after some hours. On vaginal examination nothing could be detected except an enlarged retroverted uterus.

Three days later a similar paroxysm occurred, followed by some pelvic peritonitis, with a temperature of 103° F. She began to flow a little, the discharge being watery and containing shreds of membrane. A week after she was apparently all right.

November 3d, she was seized with a third paroxysm, recurring during the next few days; she again began to flow. The pulse was 140, temperature subnormal, and the patient in a semi-conscious condition. On vaginal examination a tumor could be detected on the right side; the uterus was still larger and retroverted, with pulsating vessels about the cervix and vagina. The bowels were tympanitic, and the tenderness, at first localized in the right side, extended over the entire abdomen. The temperature rose to 103° F. The diagnosis was made of extra-uterine pregnancy, and laparotomy advised.

November 6th, the abdomen was much softer and fluctuation present on percussion; the abdomen was flat anteriorly, with tympanitic areas posteriorly. The hypodermic syringe detected uncoagulated blood.

The diagnosis was made of rupture of the sac and effusion of blood.

The next day the abdomen was opened by Dr. Packard, of Boston. The abdomen was filled with coagulated blood, and there was a large mass on the right side, which proved to be the placenta, with ruptured tube and ovary. The fœtus was not found. The mass was removed by the fingers and thermo-cautery, with but little hemorrhage, and the abdomen thoroughly washed out with warm water, and a drainage-tube passed into Douglas's sac; the wound was closed, and an aseptic dressing applied. The tube was removed on the seventh day, and the wound healed promptly. The pulse at the time of the operation was 140. After the operation the pulse and temperature ran a very irregular course for two months, the pulse reaching 130, temperature, 103.5° F., after which it returned to normal. This could be accounted for by the presence of cellulitis. The patient to day is perfectly well and healthy.

Case II.—Mrs. M. E. S——, aged forty-eight, had noticed for two years enlargement of abdomen, which caused much dyspnœa. July, 1890, she consulted a physician, who removed by aspiration fifty two pounds of clear, straw-colored fluid. From this time to November 25, 1890, nearly three hundred pounds of fluid were removed. The heart, lungs, and kidneys were normal; when the abdomen was filled with fluid the kidneys acted but little. Menstruation was regular; there was much œdema of the lower limbs, none of the upper. She was very feeble, being able to sit up but little. Nothing could be detected by vaginal examination, but by rectal examination a tumor could be detected high in Douglas's cul-de-sac. The diagnosis was made that the ascites was due to the pressure of the tumor on the iliac veins. A laparotomy was performed November 27, 1890, and a hard, nodular tumor, nearly the size of a child's head, was discovered wedged into Douglas's cul-de-sac. It was invested by a thin membrane and attached to the left ovary, which formed its nucleus; there were some adhesions. The uterus and other ovary were normal. The adhesions were broken up and the pedicle severed by the thermo-cautery; some hemorrhage followed. The abdomen was thoroughly irrigated with hot water, and a drainage-tube passed into Douglas's sac. The wound was closed and an antiseptic dressing applied; for the first thirty-six hours a large amount of bloody serum exuded, and the patient was in extreme collapse, pulse less, and vomiting incessantly black-coffee-ground looking material. Brandy and digitalis were given by both enema and hypodermic injections. She gradually improved, and the discharge of serum completely stopped on the fourth day. The tube was then removed and the wound was entirely healed on the seventh day.

She rapidly improved and has since had no return of the ascites, and is now able to do her housework. The temperature at first was subnormal and rose to 100° F. on the third day, after which it became normal. The pulse on the third day was 100, and after fell to 80.

September 17, 1891.

A CASE OF POISONING BY CYANIDE OF POTASSIUM—RECOVERY.

By F. W. HIGGINS, M.D.,

CORTLAND, N. Y.

The virulence of cyanide of potassium as a poison, and its rapidity of action, are well known. It is stated that five grains have caused death, but in a case to which I was recently called recovery took place after a much larger amount had been taken into the system. The estimate of the amount is approximate indeed, as it must be in cases of poisoning generally; still, in this case I think the margin of error is not large.

Mr. X——, aged thirty, druggist, at the first opportunity after a sudden family quarrel, took from a can of cyanide of potassium a piece larger than a lima-bean, threw it into a graduate with two ounces of whiskey, and drank it off. He immediately began to feel queer, "as if he were only two feet high," got upstairs, where he locked himself into a small room, and threw himself on a couch. In about ten minutes his partner discovered that he was inside and had the door broken open. His face then was purple, the pupils were dilated, the breathing was puffy. The man's eyes were wide open, but he was unconscious and bathed in a profuse perspiration. Whiskey, ammonia, and emetics were administered. No vomiting could be provoked. In fact no vomiting took place until four hours later, when he began to revive and when I first saw him. No one knew what poison he had swallowed, so no special antidote was administered. He was evidently sinking rapidly, when hypodermics of ether were suggested, which seemed to have an immediate effect upon the pulse and respiration. When I arrived, in response to a telegram, he could answer questions rationally but with difficulty. The skin was still cyanosed and the pulse very feeble. He then told me what he had taken, and how large a piece. Since his recovery, which is complete, he has kindly selected for me a piece as nearly as possible the size of that he took. It weighs 19½ grains.

The drug had been in the store for over a year, but kept in a tight tin can. When we remember that at least fifteen grains were taken, about four hours after the last meal, and that no antidotes were used except stimulants, we must regard the case as remarkable.

The whiskey which he took with the cyanide very probably was a factor in the case, assisted perhaps by the hypodermic injections of ether.

Surgeons Judged by a Surgeon.—An amusing incident, at the expense of M. Desprès, the well known Member of Parliament and surgeon to the Charité Hospital, as well as the unflinching opponent of Lister and all his works, took place at a recent debate in the Chamber of Deputies. M. Pelleton, in the course of a speech, remarked that the *rôle* of the Government ought not to be like that of the patient who, suffering from an incurable malady, goes to consult a surgeon, but, arrived at the door, dare not enter. M. Desprès: "That is often the best thing he could do." M. Pelleton: "The honorable member is without doubt in a better position than anyone to know the danger one runs in seeking a consultation." [General hilarity.] The President: "I beg of you, M. Desprès, to observe professional secrecy." [Renewed laughter.]

MEDICAL RECORD:

New York, December 5, 1891.

TYPHOID FEVER AND THE OYSTER.

THE aristocratic zymotic diseases have usually been found to be diphtheria, pertussis, and scarlet fever. These attack the upper classes of society relatively more than the lower. In England, however, typhoid fever has secured an enviable pre-eminence through its having found a nidus in the heir-apparent, and quite recently in his son. These distinguished and useful persons ran great danger to their lives, and this is a fact which we must of course deplore. But the establishment of the typhoid lesion in the royal ileum did, on a former occasion, give a great impetus to the study of the disease, and more particularly of sewage and plumbing. The recent illness of Prince George has started investigation in a new line; for it has been intimated that he contracted his fever by eating oysters gathered from beds poisoned by sewage. In consequence of this, it is stated that the consumption of oysters has fallen off one-half in London. As the United States is a much greater oyster country than England, there is no doubt that investigations of our oyster beds will be made. It is most improbable that any dangerous and unsanitary conditions will be found. There are, so far as we know, no large oyster-beds in the neighborhood of large towns or their sewage outlets. Besides this, typhoid fever generally begins to lessen in amount as the oyster season starts in. Still, a bacteriological study of the oyster might prove interesting.

THE HEALTH OF TRAINED NURSES.

THE popularity of the trained nurse is not in any way diminishing. We learn that another training-school is to be organized in connection with one of the hospitals of the city, and in the report of one of the already established schools it is stated that not half the calls could be supplied. In this same school there were four hundred applicants for positions as pupils, from which number only twenty-five could be selected.

We note one statement, however, of rather unfortunate significance. In a school containing about fifty pupils the average number constantly sick was about three per week, or six per cent. Now, the average sick-rate of selected adults is very much below this. In ordinary benefit societies, for example, there are less than three constantly sick to every death, and this includes a very wide range of ages. It seems as if nursing was a peculiarly severe tax on the physical strength of women, or else that the methods of training nurses and of caring for their health are lacking in some ways. Young women who are enthusiastic and earnest in their work are usually very forgetful of their own comfort and health. Those who engage them are also often thoughtless, expecting that a professional nurse should endure any amount of physical fatigue and strain. The work itself of the nurse is not essentially healthful, but rather the reverse. All these facts should make it incumbent on those managing training-schools, to select only healthy young women as pupils, and to instruct them sedulously as to the importance of caring for their own physical condition.

DISAGREEING BACTERIOLOGISTS.

THERE is a beautiful "row" in the German bacteriological world, and all about tuberculin. Professor Koch, in his recent communications about this interesting substance, reproaches his colleagues for not making investigations themselves instead of waiting for him to finish the work. He ignored the fact that such work had been done by Cheyne and Hunter, Nencke and Hammerschlag, and others. Therefore Professor Koch now receives a merited visitation of wrath from Professor Hueppe. This latter gentleman asserts that Koch's two recent communications contain nothing that had not been independently shown by others, while they do not go so far even as other work has in the isolation of the active principle of tuberculin. He quotes Professor Koch's earlier criticism of M. Pasteur against his own present methods of publication of his researches. Finally, Dr. Hueppe deals severely with the accusations brought by Professor Koch against bacteriologists in general, and shows how ill-founded they are.

DO DOCTORS DISAGREE?

THE *Medical Mirror* reprints from a recent issue of the *Sunday Mirror* the following comments upon the recent meeting in St. Louis of the Mississippi Valley Medical Association: "The Mississippi Valley Medical Association favored St. Louis with one of its official sittings and as usual when there is a gathering of the sons of Æsculapius much bad feeling cropped out among the resident medicos. A few saw in the preliminary arrangements for the reception and entertainment of the delegates an effort to boost a certain college into undue prominence; others detected a movement on foot to extend the hand of professional fellowship to a member of the surgical corps who was personally distasteful, or whose reputation was too brilliant, or because the methods by which he managed to have himself constantly written or talked about were not in accord with the strict requirements of professional etiquette. Some had one excuse and some another for frowning upon the whole thing and withholding their patronage and gracious presence from the assemblage. All of which, it may be remarked with truth, was exceedingly silly and childish, and not calculated to reflect a particle of credit upon those who sulked in their offices and planted themselves on their professional dignity."

Our well-burnished and reflective medical contempo-

rary makes some comments upon the foregoing which are unjustly and unnecessarily apologetic. The rather prevalent idea that doctors are always quarrelling and disagreeing is one which has been handed down from ancient days, but is not true of the educated profession of to day. There was a time perhaps when consultations were just short of free fights, and when disagreement and disputation over the sick-bed were the rule. This is certainly not the case to-day, except, perhaps, in some darkly shaded areas of the earth's surface. We have even heard it said that Chicago physicians were stalwart supporters of each other's character, and if it were not for Cook County Hospital a millennial peace would prevail over the crust upon which the tall buildings of that city vibrate. And St. Louis cannot be behind Chicago in matters of social intercourse and the higher ethics. The very numerous meetings of medical men throughout the country are, with few exceptions, conducted with dignity, and discussions are rarely acrimonious. Doctors do sometimes disagree and quarrel, just as the rest of the world does, but for a class of men thrown in contact with each other as often as is the case with physicians the amount of disagreement and ill feeling is not great, and with increase in enlightenment it is growing smaller.

We contend that the old adage that doctors always disagree is not applicable to the modern profession, and we regret that our St. Louis contemporary does not take this view. Is there an extra acidity in the atmosphere of the Mississippi Valley?

TUBERCULOCIDIN.

While Koch believes that tuberculin has no destructive effect on the bacillus, recent work by Klebs seems to show that this may not be entirely the case. Klebs has isolated a substance from crude tuberculin, which he calls tuberculocidin, and which is claimed to act specifically on the bacilli. The tuberculocidin is an albumose, and it, or its combinations with tannin or other precipitants, has an undoubted effect in tuberculosis, never exciting fever, and producing marked improvement. Hectic and night-sweats disappear; signs of catarrhal process in the lungs, together with cough and expectoration, rapidly diminish; appetite and body-weight increase. The bacilli in the sputum are said to become granular, and less and less capable of receiving the staining reagents, and finally disappear. In observing the effects of the use of this "tuberculocidin" Professor Klebs is being assisted by Dr. C. Spengler, of Davos, and Dr. Nolda, of Montreux.

THE PAN-AMERICAN MEDICAL CONGRESS.

The Committee on Permanent Organization of the Intercontinental American Medical Congress, which met in St. Louis in October, did some excellent work. It may now be regarded as settled that the Congress will be held, and if the Committee acts as wisely in the future as it has in the past, there can be little doubt of its success.

There was at the start a slight unpleasantness arising from a misunderstanding in regard to a delegate from one of the public services, but it was only an incident, and as the Committee was seemingly in the right in the action it took, nothing more need be said about it. One excellent move was the discarding of the clumsy title, "Intercontinental American Medical Congress," and the adoption in its stead of the more familiar and euphonious "Pan American Medical Congress." Washington was very properly adopted as the place of meeting of the Congress, and the first Tuesday in October, 1893, was the date selected. The rules for the government of the Congress are to be printed in English, Spanish, and French, but why the last-named language was selected, while Portuguese was omitted, is not very apparent. French is spoken in a portion of Canada, in some of the smaller West India Islands, and in a narrow strip on the coast of South America, whereas Portuguese is the language of the largest and one of the richest and most progressive of the South American republics. If French is admitted, why not also Dutch, since several of the islands in the West Indies, as well as one division of Guiana, belong to Holland. We do not know whether the deliberations will be allowed in these three languages or not, but hope that they will be restricted to English and Spanish. These are the preponderating tongues on this continent, and confusion can only arise from making the Congress a polyglot affair.

This is, however, a minor detail. The Congress is to be held, and we hope and believe it will be a success and will help to draw closer together not the physicians alone, but all the members of the two great races who people this immense continent. And whether the proceedings be in two languages or twenty, the Medical Record will be on hand as usual, and will present its readers with a full and accurate report of all that is said and done.

VAGARIES OF THE HUMAN TEMPERATURE.

Some wonderful stories have been passing through the medical press concerning high temperatures of the human body, so high as to be beyond measurement by the best registering thermometers procurable, the ordinary clinical instruments, graduated up to 115° F., being shattered by the expanding mercury. Indeed in some cases, if we may believe the concurrent testimony of several reliable witnesses, the blood was nearly at the boiling-point, and the hot room of a Turkish bath would have been, as it were, a refrigerator to the hyperpyrexic individual. What became of the albuminous constituents of the circulatory fluid under these circumstances is, however, not stated.

Now, while we may be permitted to doubt the accuracy of these observations of such extreme cases, being forced to believe, not in the dishonesty of the observers, but in the presence of some fallacy undiscovered by them, there are, nevertheless, a number of instances on record, usually in hysterical persons, in which the thermometer registered from 110° F. to 115° F., whatever the actual temperature of the patient may have been, where the accuracy of the observations cannot be questioned. There was a case of the sort seen in a hospital in this city in 1877 or 1878, in which repeated observations made by different physicians with different instruments, under the most careful scrutiny to detect fraud, gave a temperature of 112° F. to 115° F. We do not remember ever seeing a published report of the case, but it was seen by a number of physicians in the city, and the notes are recorded in the

case books of the hospital. If the thermometer in these cases is a true index of the actual temperature of the patient's body, then we must revise the dictum which makes a recorded temperature of 110° F. one of fatal prognostic import.

Another even more curious freak of temperature is recorded by Dr. J. A. Austin in *The Lancet* of October 24, 1891. A primipara, twenty six years old, of a remarkably cool, unexcitable temperament, was confined on Sunday, October 4th. "Labor was normal, and the case progressed without one bad symptom till the following Saturday, even the infant exhibiting a disposition to take things easily, so unlike new-born cherubs. On the Saturday, however, there was a temperature of 102° F. in the right axilla; pulse 80; skin cool; respiration easy; lochia and milk normal; no constitutional disturbance whatever. The temperature was then taken in the left axilla, and it was normal. The following day the thermometer registered 104° F. in the right axilla; normal in the left. On Monday it fell again to 102° F., and on Tuesday it was normal on both sides. From beginning to end the patient was singularly free from bad symptoms, and made an uninterrupted recovery."

Another singular case of unilateral elevation of temperature was reported in *The Lancet* some five years ago. The patient was a young woman who was admitted to the Edinburgh Infirmary complaining of dizziness and pain in the left side, and with a purpuric rash covering the lower extremities. Soon after admission she had a fright, and on taking her temperature that night the physician found that the mercury stood at 111° F. The next day at four P.M. the temperature was taken with a thermometer in each axilla, the one on the right side indicating 108° F., that on the left 99.4° F. Near midnight of the same day this was almost exactly reversed, the temperature on the right side being 98° F. and that on the left 108° F. It varied in this way for several days, first one side, now the other, indicating several degrees, in one case more than 12, higher than the other. The subsequent history was one of hysterical pains, wild delirium, etc., from which the patient finally recovered, still remaining emotional, however.

Professor Horsley stated at a meeting of the Neurological Society of London that he had found, from an analysis of some eighteen cases seen by him, that a notable difference in temperature of the two sides of the body occurred in cases of brain disease in which the lesion was situated in what he called the corpus striatum frontal plane of the hemispheres, this passing, on the surface of the cortex, through the ascending frontal gyrus. With rare exceptions in these cases the rise of temperature was on the side of the body opposite to the lesion. Dr. H. Percy Dean said at the same meeting that in certain cases of compression of the brain there is a difference in the temperature of the two sides of the body, the higher temperature being on the same side as the compressed area when that was large, and on the opposite side when it was small.

In the case reported by Dr. Austin, however, there was no hysterical element, neither was there any evidence of brain lesion as in the cases analyzed by Mr. Horsley. The solution of the problems raised by very high temperatures in hysterical persons, and by the occurrence of unilateral temperatures, is one that can be made only by means of much clinical and experimental work. But the problems are exceedingly interesting, and will amply repay study and painstaking investigation.

A NEW DIAGNOSTIC SYMPTOM OF CARCINOMA OF THE STOMACH.

In the *Revue de Médecine*, October, 1891, Dr. R. Lépine dwells on the not infrequent difficulties in making a diagnosis of cancer of the stomach, and states that one important and characteristic symptom is a diminution in the globular richness of the blood. This symptom is particularly helpful in distinguishing cancer from pernicious anæmia, because, as he states, in the latter disease the globular richness of the blood is not lessened. He finds that in gastric cancer the diminution of the blood-cells often reaches as much as one-half; and in that respect differs from the ordinary anæmic conditions associated with nephritis, phthisis, rheumatism, etc., where the loss of red blood-globules, though present, is less marked. Dr. Lépine cites the investigations of Benoist-Jeanin in support of his view, and reports the histories of six cases of cancer of the stomach, in which the number of blood-cells ranged from 1,500,000 to 2,000,000, or more rarely 3,000,000, cells per cubic millimetre. This condition, Lépine admits, does not occur until the disease is "a little advanced," and hence its value as a symptom cannot be considered a very high one.

News of the Week.

Vaccinated Against Snakes. — Dr. Jacolot, in "Archives of Naval Medicine," states that at Tuxpam, on the Gulf of Mexico, there are men called "Curados de Culebra" (safe from vipers), who may be bitten by venomous snakes without effect, as they have been previously inoculated with the poison of these animals. Jacolot relates, in detail, how these vaccinations are practised. The patient takes first the bulb of a native plant called "mano del sapo" (toad's hand), a Dorstenia. Then the inoculation is made with the venom-tooth of one of the most poisonous snakes. Dr. Jacolot was at Tuxpam in 1867, and found this preventive inoculation an old practice among the natives of that region.—*The Satellite.*

Dr. G. D. Dunham, of Plattsburg, N. Y., died on November 29th, of heart disease.

Mr. Wharton Jones, of Ventnor, England, well known for his physiological and pathological studies, died on November 2d, aged eighty-four.

Professor Billroth on the New Rifle.—In a recent lecture Professor Billroth spoke on the effect of the new rifle in war, and declared that the ambulance department in Austria would be absolutely inadequate to deal with the vast number of the wounded.

In Founding Koch's Institute for Infectious Diseases, Dr. von Gossler, then Prussian Minister of Ecclesiastical, Educational, and Medical Affairs, stipulated that all the investigations made there should be published. The first publication saw the light a week or two ago in the

Deutsche Medicinische Wochenschrift, and its author is Professor Ehrlich, who has long been one of Koch's fellow-laborers. It treats of abrin, a poisonous albuminous body, against the noxious effect of which animals can be rendered immune by strong dilutions of it.

The Number of Medical Students in Germany.—The number of students who matriculated in the twenty universities of Germany and the Academy of Münster last term, was 28,515, of whom the largest contingent—namely, 8,916—were students of medicine.

The Snake War in India.—In the year 1890 the snakes of India killed 21,412 people, while people killed 510,659 snakes. The people, mostly natives, are therefore ahead, but the snakes are making a serious fight and many heels are chronically sore.

A Dispensary for Medical Mesmerism is one of the advertised features of the metropolis. It is conducted by a clerical gentleman, who has of course had "thirty years' experience." Yet medical mesmerism is a little more honest than faith-cures and the laying on-of-hands.

Baldness and the California Climate.—According to the veracious chroniclers of the daily press, residents of California mostly get bald and lose the goodness of their teeth before they are forty. Yet we are also told that in California there is no phthisis, arteritis, apoplexy, or premature senility. One must take the choice, then, between long life and a toothless one, or a short life with plenty of hair and molars.

A Bogus Medical Diploma Mill.—The Cincinnati papers announce the arrest of a Dr. (?) Van Vleck on the charge of issuing medical diplomas, the institution that issues the diploma going by the name of "The Medical University of Ohio."

To Secure Medical Legislation for Ohio.—The *Cincinnati Lancet-Clinic* announces that the physicians of Cinnati have appointed committees to act together for the purpose of obtaining medical legislation this winter.

Verdict Against a Druggist.—In a suit for $10,000 damages brought against a Brooklyn druggist, in consequence of the substitution of corrosive sublimate for [illegible] compounded by a clerk losis. The especial feature of the paper was a report of a case which occurred in his practice, and in which he pointed out the difficulty of diagnosis in this obscure disease and gave an outline of the methods for microscopic examination, together with the best methods of cultivating the bacillus of glanders. The paper recommended that, for preventing glanders, persons who came in contact with horses having open sores or discharges from the nose should disinfect the hand with a solution containing a tablespoonful of equal parts of glycerine and carbolic acid in a quart of hot water, or ten grains of corrosive sublimate in a quart of water. In his report of the fatal case which he had treated, that of a painter who became inoculated through a sore on the hand while handling an horse, suffered rupture of his left ligamentum patellæ. A surgeon attended him for two months or more, during a portion of which time the patient did some of his farm work. The union proved to be ligamentous, and was, perhaps, two and one-half inches long. The patient brought suit to recover $10,000 for malpractice. At the close of the prosecution, counsel for defence moved a non-suit on the ground that the evidence had failed to show that the present condition of patient's patella was in any manner due to neglect or non-skilful treatment on the part of defendant. After some argument, the Court decided to hear the defence and then give an opportunity for renewal of the motion. Much valuable expert evidence was given, to the effect that the result was a fair average, and that the defendant had properly treated plaintiff's fracture. As the evidence of both plaintiff and his expert was substantially the same as that of the defendant and his experts, the Court directed the jury to bring in a verdict of no cause of action.—*Boston Medical and Surgical Journal.*

The United States Medical Practitioners' Protective Alliance.—The *Maryland Medical Journal* says editorially: "According to the published statement of the Medical and Chirurgical Faculty of Maryland (in its Transactions for 1890, p. 119), the 'founder' of the 'United States Medical Practitioners' Protective Alliance' was expelled in April, 1890, from the State Medical Society of Maryland, for violation of its Code of Ethics (identical with the Code of the American Medical Association); the offence, which is not there stated, being that he advertised himself in the daily papers, giving as an endorsement his membership in the Faculty, and refused to discontinue advertisement. The 'President' of this 'Alliance' is now (according to a hand-bill distributed through the city, of which a copy is now before us) Medical Director of the 'National Bureau of Medical, Surgical, and Hygienic Relief of Baltimore City,' the successor and heir of the 'Bureau of Medical Relief' whose principles and practices, as stated in the editorial columns of the *Journal*, September 12, 1891, are utterly condemned by all physicians of standing in Baltimore with whom we have conversed on the subject."

London Pauperism.—Census of metropolitan paupers, exclusive of lunatics in asylums and vagrants, taken on the last day of the weeks named hereunder (enumerated inhabitants in 1881, 3,815,000): First week of November, 1891—indoor, 57,581; out-door, 32,425; total, 90,006. First week of November, 1890—indoor, 57,552; out-door, 33,766; total, 91,318. First week of November, 1889—indoor, 58,354; out-door, 35,556; total, 93,910. First week of November, 1888—indoor, 58,834; out-door, 38,747; total, 97,581. (These figures exclude patients in the fever and small-pox hospitals of the Metropolitan Asylum District, the number of whom on the last day of the week was returned as 1,795 in 1891, 2,407 in 1890, 1,691 in 1889, and 1,000 in 1888.) Vagrants relieved in the metropolis on the last day of the first week of November, 1891: Men, 703; women, 196; children under sixteen years of age, 23; total, 922.

Decimal Weights and Measures.—A communication has been received from the British Consulate at St. Petersburg to the effect that in Finland the use of metric weights and measures will shortly be compulsory. For some time past there has been a decimal coinage, and the metric weights and measures have been obligatory for the Custom House, the State railways, the Post-office, and pharmaceutical chemists, but after December 31st next, the old system of weights and measures will no longer be permitted in any public or private establishment. The measurement of public roads has already

been changed from versts to kilometres. In Russia the metric system of weights and measures is already used by medical men and chemists.

Dr. Edmund Charles Wendt, our Riviera commissioner, while in London, entertained at dinner, at the Savoy Hotel, Mr. Ernest Hart, of the *British Medical Journal*. Among the other guests were Mr. Harold Frederic, Mr. Frank Marshall White, Mr. Bloomenfield, all of London, and Mr. Richard L. Kemble, of New York. Sir Morell Mackenzie was unavoidably absent, owing to a recent indisposition.

The Influenza in Europe.—Influenza in its most virulent form is raging in Bordeaux. Few families are exempt from the sickness, and many deaths, principally of aged people, have occurred. The number of cases of influenza in St. Petersburg has increased so rapidly that there is now quite an epidemic. The city hospitals are full of patients. Two years ago the disease was almost exclusively among the poor, but this year it claims its victims chiefly from the higher ranks of society.

An American Magnet in London.—The performances of Miss Abbott, the so-called "Georgia Magnet," are the latest craze in London. The medical faculty declare themselves to be non-plussed concerning her mysterious powers. Twelve years ago the readers of the RECORD were fully informed as to the scientific merits of this performer in the Lulu Hearst line of trained muscle-reading. A great many Londoners are not yet readers of the RECORD, or there would be less stir about our countrywoman, whose exhibitions in New York, it will be remembered, fell rather flat, and were fully exposed in the medical and lay papers.

The Medical Society of the Missouri Valley.—The next meeting of the Medical Society of the Missouri Valley will convene in the City of Lincoln, Neb., Thursday evening, December 17th, and continue in session on the 18th.

The Next International Medical Congress.—It is considered likely that the date of the next meeting of the International Medical Congress, which is to be held at Rome in 1893, will be fixed for September instead of Easter, as at first proposed. The Organizing Committee has not, however, yet come to a final decision on the subject. Professor Baccelli is the President, and Dr. Maragliano the Secretary-General of the Committee. The following are the Sections of the Congress, with their respective Presidents: Anatomy, Dr. Antonelli; Physiology, Drs. Albini and Albertoni; Pathology, Drs. Foà and Bizzozzero; Therapeutics, Dr. Cervello; Clinical Medicine, Drs. Baccelli, Murri, Bozzolo, and Maragliano; Surgery, Dr. Bottini; Obstetrics, Dr. Morisani; Psychological Medicine, Drs. Morselli and Tamburini; Ophthalmology, Drs. Secondi and De Vincenzi; Dermatology and Syphilography, Drs. Campana and Barduzzi; Forensic Medicine, Dr. Tamapia; Hygiene, Drs. Pagliani, Banalis, and Belli. Many applications for membership have already been received, and the attendance is expected to be very large.

The Seasonal Prevalence of Typhoid Fever.—The *British Medical Journal* of November 19th says: "There is much reason to fear that the autumnal increase in the prevalence of typhoid fever, which long experience has taught us annually to expect, is this year of more than average severity. There are few things about the infectious fevers more striking than their seasonal prevalence. We know that some—such as typhoid fever and diphtheria—are due to infection by specific microbes, and we surmise the same to be true of all. We know also that the insanitary conditions which favor the spread of the infective principle of typhoid fever are always present—in March and April, as widely as in October and November, yet the number of cases in the former months is scanty, in the latter large. The fact is so well known that it is hardly necessary to prove it; but if further proof is wanted, it may be found in the Statistical Report of the Metropolitan Asylums Board published this week. The admissions of patients suffering from typhoid fever have been recorded month by month since 1872; the numbers, it is found, have fallen to the *minimum* three times each in March and April, five times in May, seven times in June, and once in July; they have risen to the *maximum* once in September, eleven times in October, six times in November, and once in December. In tropical and sub tropical regions the hot months are the typhoid season."

Frequency of Criminal Abortions.—Judging from the reports in the daily papers, criminal abortions are quite frequent. It is a comfort to know that the practice is limited to irregular practitioners, who are duly apprehended when the regular medical man is finally called to the dying patient. And yet there has not yet been found a way to prevent the advertising of the scoundrels in the leading public journals.

The Meeting of the Italian Surgical Congress was held in Rome from October 25th to 27th, under the presidency of Professor Durante, Senator of Italy.

Malpractice for the Opium Habit.—A medical gentleman of Dakota has been sued for malpractice in causing the opium habit in a patient. If this should hold, how many suits might be brought for the alcohol habit?

Monument to Dr. Henry Bennet.—Mentone, France, is proposing to erect a monument to Dr. Bennet, "who did so much to promote the prosperity and welfare of that admirable resort." Dr. Jacolot was at Tuxpam in 1867, and found this preventive inoculation an old practice among the natives of that region.—*The Satellite.*

Dr. G. D. Dunham, of Plattsburg, N. Y., died on November 29th, of heart disease.

Mr. Wharton Jones, of Ventnor, England, well known for his physiological and pathological studies, died on November 2d, aged eighty-four.

Professor Billroth on the New Rifle.—In a recent lecture Professor Billroth spoke on the effect of the new [illegible] and declared that [illegible]

Another Death from Chloroform has been reported in London at the King's College Hospital. The operation to be performed was a trivial one for suppurative cellulitis of the leg. The patient, a male tramp, aged twenty-six, was recovering from a drinking bout, and had not partaken of food for three days. At the autopsy fatty liver and fatty heart were discovered. Death was sudden and without warning.

Society Reports.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Nineteenth Annual Meeting, held in Kansas City, Mo., October 20, 21, 22, and 23, 1891.

First Day, Tuesday, October 20th.

The Association convened in the auditorium of the Warder Grand Opera House, and was called to order at 10 A.M. by the President, Frederick Montizambert, M D., F.R.C.S., D.C.L., of Quebec.

Prayer was offered by the Rev. Samuel N. Neel.

After considerable preliminary work, the reading of papers was proceeded with.

The Cause and Prevention of Infant Mortality.—Dr. C. D. McDonald, of Kansas City, read a paper on this subject. He gave statistics showing that infant mortality soon after birth was twenty per cent. One of the principal causes was the exposure to a low temperature—a chilly room—soon after birth. He had been present when it was necessary to wear an overcoat in a room where a newly-born child was exposed to bathing. Forcing sleep by soothing syrups to overcome the effects of this exposure was another evil. Another trouble was the forcing of food, such as crackers, and water, and whiskey into the young, inert stomach of the newly-born. The mother who refused to nurse her child from selfish reasons deserved the censure of the community. Statistics show that in the first year the infant mortality, when the child is fed by artificial food, is fifty per cent. With natural food the mortality was but ten per cent. The best artificial food was the pure cow's milk. Sterilization by chemical process was not thoroughly a success because vital principles cannot be supplied by chemical process, but sterilization was preferable to impure milk.

No starchy substance could be digested in the infant stomach. Starchy infant food is converted by the chemical processes of the stomach first into sugar, then alcohol, and then acetic acid. No sensible farmer would attempt to feed a calf hay. Hay is the natural food for a cow as much as solid food is for a man. Improper dressing—thin clothes—was also a prolific source of infant disease.

Professor W. W. Daniells, of Madison, Wis., thought that no one should be allowed to sell milk in cities unless he put his dairy establishment under the control of the sanitary authorities.

Glanders in Man was the subject of a paper by Dr. Joseph Sharp, of Kansas City, Mo. The doctor classed glanders with acute infectious diseases, such as tuberculosis. The especial feature of the paper was a report of a case which occurred in his practice, and in which he pointed out the difficulty of diagnosis in this obscure disease and gave an outline of the methods for microscopic examination, together with the best methods of cultivating the bacillus of glanders. The paper recommended that, for preventing glanders, persons who came in contact with horses having open sores or discharges from the nose should disinfect the hand with a solution containing a tablespoonful of equal parts of glycerine and carbolic acid in a quart of hot water, or ten grains of corrosive sublimate in a quart of water. In his report of the fatal case which he had treated, that of a painter who became inoculated through a sore on the hand while handling an afflicted horse, the speaker aroused much interest.

Dr. Paul Paquin, of Battle Creek, Mich., in the discussion, reported a collection of seventeen cases of glanders in man, which he had collected in the State of Missouri while living there. As an instance of the virulence of the poison, Dr. Paquin told of one man who, driving behind an affected horse, was struck in the eye by a spray from the beast's nostrils, a case of glanders developing rapidly and terminating in the man's death.

The Necessity for more Stringent Legislation to Repress Empiricism.—This was the title of a paper by Chief Justice Horton, of Kansas. He said that the mountebank of the nineteenth century, with brazen face and clarion voice, travels the length and breadth of the land proclaiming himself as Diamond Dick, Indian Bill, Big Chief, or by some other equally euphonious and ambiguous title, as he asserts his skill and disposes of his wares. It might not be justifiable homicide to compel him to swallow his own darksome nostrums, but the present laws are insufficient for his repression and, however beside himself he may become, we can hardly hope that he will so far forget his villany as to administer unto himself that which he so recklessly deals out to others.

To protect the public, the American Public Health Association should recommend the enactment of statutes excluding from the medical profession those who are not competent by learning, skill, and experience to practise, and punishing by imprisonment any who violate the provisions. No one should be permitted to practise medicine or engage in surgery unless authorized to do so by a competent board of Government or State examiners.

Dr. R. Harvey Reed, of Mansfield, O , said it was no easy matter for the medical profession to eradicate quacks or pretended medical men. Whenever a question of this kind was brought before the Legislature, the profession had to contend with two prominent factors, viz., the quacks themselves, who furnished large quantities of money, and second, the general press of the country. Why the press? Because the quacks paid the newspapers more money for advertising than the regular medical profession, consequently the press aided the quacks in trying to down the law.

Water-supply and Public Health.—Mr. Allen Hazen, of Lawrence, Mass., read a paper on this subject in which the author dwelt principally upon the typhoid fever and cholera germs which infect impure water. Typhoid fever and cholera bacteria are taken into the system through food and drink. Pure water is therefore a necessity. If water is absolutely free from sewage it can be depended upon as being comparatively pure, although many waters not polluted by sewage have been known to breed disease. Flowing streams will partially purify themselves. Reservoirs and long channels where water flows and becomes aërated will not always purify it. Some system of filtration is therefore imperative, and the question to be decided is the best means of filtration. Several systems were described, but all were said to be more or less defective.

At the close of this paper, Dr. Henry B. Horlbeck, of Charleston, S. C., presented some vital statistics from the Southern States, showing the death-rate among the colored population to be much greater than that of the whites, and offered a resolution asking the governmental statisticians in preparing their reports to arrange them so that this fact may be shown. No action was taken on the resolution.

At the evening session appropriate addresses were delivered by Governor David R. Francis, of Missouri; Governor L. U. Humphrey, of Kansas, and the Hon. John T. Peak, of Kansas City, Mo.

President's Address—Dr. Frederick Montizambert, of Quebec, then delivered the annual address. He said, to the medical men of Kansas City and its vicinity, the meeting was meant in part as an appeal to quicken interest in the more purely preventive work of the profession, to increase interest in the organization and working of the coast quarantines and health boards by which people are affected; the sewerage of cities; the disposal of garbage and refuse; the purity of water-supply; the infectious diseases of animals now known to be closely related to those of man; as well as other much broader questions of modern sanitation.

To the non-medical of all ages, sexes, and conditions it is an appeal to take a lively and an active part in the great crusade against dirt and disease. In the words of Sir Spencer Wells, "Instruct your mayor and corporation, your clergy, and your own household, that every

case of typhoid fever or scarlatina, of diphtheria or small pox, of measles or whooping-cough, can no longer be looked upon as natural and providential; but that the existence of such preventable diseases is a proof of ignorance and negligence, and a disgrace to the country, to the town, and the family."

Everyone can do a little, if only to make one home or one room bright, more cleanly, and more wholesome. Sunlight, pure air, and thorough cleanliness are natural enemies to disease germs. These cannot live where they have not their proper food, which is found in dampness, darkness, mould, and dirt. The experiments of Koch, Ransome, and others prove that the living germs of consumption, when exposed to the sunlight, lose their vitality in a few hours, or even in a few minutes, if the layer in which they are exposed be thin enough, and that even ordinary daylight, if it last long enough, will have a similar effect. There is no sounder philosophy than the old saying that, "there is more health in a sunbeam than in drugs, more life in pure air than in a physician's skill," and that, "sunlight may fade your carpets, but better that than have its absence fade your cheeks."

The President then paid a tribute to the memory of such members of the Association as had died since the last annual meeting. He then passed on and briefly reviewed the various contagious diseases as battled with by the health authorities of the country, together with the experiments entered into to overcome them. Asiatic cholera, la grippe, cancer, and diphtheria were all touched upon, as well as disinfection and immunity.

Second Day, Wednesday, October 21st.

Vaccine and Vaccination was the title of a paper read by Dr. Paul Paquin, of Battle Creek, Mich. He touched first upon the necessity for absolutely pure vaccine, and told of some of the diseases that accrue from impure vaccine. The doctor had tested, on rabbits, guinea-pigs, and fowls, over one hundred vaccine specimens. In these tests he said he had found such cheerful forms of bacteria as the bacillus pyogenes fœtidus, the staphylococcus pyogenes aureus, the bacillus septicus, and gangrene micrococci. These he said produced abscesses, gangrenous lesions, septicæmia, and pyæmia.

Dr. Charles N. Hewitt, of Red Wing, Minn., spoke of unfavorable results from using bad vaccine in his State, and of the difficulty in obtaining good vaccine, and gave his personal experience. Small-pox, he said, is the same as it always was. An epidemic might sweep the country now, as the country was practically unprotected.

Dr. Yesi, of Mexico, spoke of the compulsory vaccination of Mexico. Human vaccine alone was used. Lower animal vaccine is not cultivated. Better results from human than animal vaccine are obtained. A serious small-pox epidemic has not visited that country in about twenty-five years.

Dr. L. F. Solomon, of New Orleans, La., replied that in Louisiana each child must show a vaccination certificate before being allowed to attend school. About ninety per cent. of the primary vaccinations were successful. He favored the use of bovine virus.

The Disposal of Garbage and Refuse.—Dr. Delos Fall, of Albion, Mich., read a paper on this subject. He spoke of the intimate relation between typhoid fever and the accumulation of waste organic matter. The method used in New York is taking the waste out to sea and dumping it. Philadelphia recommended cremation. Chicago objected to the use of waste in filling holes and vacant lots, and then building houses on them. San Francisco recommends cremation. Baltimore has dumps which are objectionable, and which will be removed as soon as a better method can be found. Cincinnati gives its waste to a desiccating company, which is under contract to remove the same. In Charleston the city removes its own garbage; carts it out in the morning and generally gets through about noon. This waste is dumped into a salt-water marsh. The cost is about $19,000 a year. Milwaukee pays $23,316 a year for collecting garbage by hand, and $15,000 a year for disposing of the same. The Merz system of disposal of garbage is used. Garbage is at present disposed of by dumping it into Lake Michigan, much to the disgust of the citizens, because the Merz system contract has expired. In Washington the removal is carried on by the contract system.

Dr. Edward Clark, of Buffalo, N. Y., made a report on the collection and transportation of garbage and refuse in cities. He advised full police power for the sanitary service of large cities. A galvanized iron tank holding about two or three bushels is the best receptacle for holding household garbage. The refuse tank must not be placed on the street, or sidewalk, but the collector should be compelled to go in and get it, remove the contents, and replace the cover.

For transporting garbage carts are preferable for short, and wagons for long, hauls. The beds should be made water-tight, and should be flushed after each dumping. Any driver who failed to do this should be instantly discharged. The bed should be covered with iron.

Rabies, was the title of a paper read by Dr. J. J. Kinyonn, of the U. S. Marine Hospital Corps. He said the disease was transmitted almost wholly by the canine and feline species. The disease prevails all over the world, except in Australia, where it is not known. He regretted that so little is known of its prevalence. He opposed the idea that the disease is confined to warm weather, the statistics showing that the greater number of cases occur in December and May. He discussed Pasteur's system and its success. Recognition of the disease is not easy in any animal in the early stages. He advocated the establishment and enforcement of strict quarantine regulations, in order to eradicate the disease.

American Climates and their Physical Effects.—In this paper, Dr. P. C. Remondino, of San Diego, Cal., said that it is well known that European immigrants soon lose their ruddy cheeks and bright eyes, with a certain loss of spirit, when they came to this country. They lived in happy disregard of all hygiene or science. In changing climate, they followed no rational rule whatever for the really necessary change of diet. He then extolled Southern California, and compared it to the Garden of Eden.

Animal Diseases was the title of a paper read by Mr. Ernest L. Dundas, U. S. Veterinary Inspector at the Kansas City packing houses. He spoke strongly against the evil of diseased cattle being shipped to market. As soon as a farmer discovers that tuberculosis is about to ravage his cows, he immediately ships them off to market to get rid of them before they die on his hands. He recommended the police supervision of all milk dairies. He laid to the Jersey cow the blame of being most generally afflicted with tuberculosis.

Dr. Walter D. Green, of Buffalo, said that, while it might not be incorrect that the disease was quite common and deserved close watching, still the fact should only urge the physician to more earnestly fight against the spread of disease among his patients.

Dr. Peter Bryce, of Toronto, limited his remarks to tuberculosis in milk, and the manner in which the disease is most commonly transmitted to consumers. In Canada, he said, they never bred their milch-cows, and in one city they never use a milch-cow after she once goes dry; she is immediately sent to the butcher. The great question is how to tell a cow when she is so afflicted. It seemed to him that in view of the startling figures that there are 15,000,000 cows daily supplying the country with milk, and the fact that in certain abattoirs it has been shown that five to ten per cent. of the cattle killed are tuberculous, there should be a most rigid and regular inspection of all milch-cows, as is due the public.

New Organization of the Supreme Board of Health of Mexico, formed the theme of a paper submitted to Dr.

Domingo Orvananos, of the city of Mexico. In this paper the outline of work covered by the Mexican supreme board of health was given, showing a most complete system of supervision, a system which on its face would tend to make it one of the most thorough in operation in any country. One exceedingly good feature is the sending of a surgeon-physician with every ship leaving Mexican ports, who shall be held responsible for the sanitary condition of the vessel, and who shall be obliged to report to the Mexican consul at every port where the vessel may touch, and obtain from him a clean bill of health. This move was done in view of the fact that Mexico is preparing to meet the reciprocal treaties of all countries, thus calling for the service of an extensive maritime navy.

Land Habitation as a Public Health Measure.—Dr. George Homan, of St. Louis, Mo., read a paper with this title. The paper showed the benefits which would arise by the individual ownership of homes, as that would render less likely any communicable disease, as well as render easier the fight against disease by admitting of isolation, a most desirable feature in combating disease.

Third Day, Thursday, October 22d.

The Present Position of the Milk-supply Problem from the Public Health Standpoint, and Some Practical Methods for Securing Safe Public Supplies.—This paper was read by Dr. Bryce, of Toronto, and the following is a summary of the precautions necessary to healthy milk therein presented:

1. It is especially desirable that a system of periodic veterinary inspection be exercised in addition to the dairyman's inspection.

2. Strong views should be held and exercised regarding the nature and quality of food for cows. All decomposed foods, as those which are liable to undergo fermentation, should be wholly avoided. The best foods are well-ripened grains and grasses.

3. The stables of the cows are a point of great importance. Too often dark, damp, ill-ventilated, and crowded pens have been the home of this chief of our food supplies. It is quite possible to keep, even on a large scale, a dairy stable free from the ordinary disagreeable stable odors. The water-supply to the cows is of equal importance.

4. The care of the milk at the time of taking and subsequently is, of all points, at once the most difficult and the most necessary to supplying a wholesome milk. De Claux has said: "Cleanliness is everywhere the *sine qua non*." This means almost a revolution among farmers and dairymen. The sterilizing of all cans and bottles by steam or dry heat and the boiling of all strainers will be necessary.

5. The delivery of milk is of prime importance.

6. When milk has reached the consumer it must be placed in a refrigerator or promptly consumed.

Fourth Day, Friday, October 23d.

Dr. J. Ramon Ycaza, of the city of Mexico, read a paper entitled "A Few Considerations upon the Progress of Public Hygiene."

Notes on the Hygiene of Rice Culture was the title of a paper by Dr. Nazario Lomas, of Moreles, Mexico. Moreles is the great rice-producing State of Mexico, and the paper touched upon the sanitary effects of this culture. The vast rice-swamps were declared by the author to be most insalubrious.

Car Sanitation.—The report of the committee on this subject was read by Professor W. W. Daniells, Chairman, Madison, Wis. He said the great difficulty in the heating arrangement of cars was that all systems thus devised are for heating alone, and that ventilation is not particularly sought.

Dr. R. Harvey Reed, of Mansfield, O., said that if the public asked for these things, as it demanded fast trains and elegant car upholstery, it would get them.

Professor Daniells thought that cars should be made differently. Instead of covering Pullman cars with expensive tapestry, they should be furnished with rattan or leather, as the cars on some of the suburban trains.

Dr. Joseph Sharp recommended comfortable air-cushions that could be taken out and cleaned.

Dr. Charles N. Hewitt, of Minnesota, read a paper dealing with the existing methods of dealing with immigrants as respects infectious diseases in England and on English ships. He held that the notification of infectious diseases among immigrants to the United States was a duty which the National sanitary authorities owed to the sanitary service of the several States; and he cited an example of such an arrangement between the United States authorities and the State Board of Health of Minnesota.

Dr. A. N. Bell, of Brooklyn, followed with a paper on "The Bath and its Adoption."

The Executive Committee reported to the Association two important resolutions. One was by Dr. Homan, of St. Louis, declaring it the sense of the Association that State and Provincial inspection of the production of vaccine virus be established. The other resolution asks the establishment of a Federal department of health, to have at its head a Secretary of Public Health—a Cabinet officer at Washington. Both resolutions passed.

Dr. Henry B. Baker, of Lansing, Mich., introduced a resolution to the effect that the Association hold its meeting in Chicago in 1893, and that, so far as possible, the occasion be made an International Congress of Hygiene and Public Health, which was adopted.

Election of Officers.—The officers elected for 1892 are as follows: *President*, Dr. Felix Formento, New Orleans, La.; *Vice-Presidents*, Drs. Walter Wyman, Washington, D. C., and Domingo Orvananos, of Mexico; *Secretary*, Dr. Irving A. Watson, Concord, N. H.

Next place of meeting, City of Mexico, date to be fixed by the officers of the Association.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, May 27, 1891.

H. M. Biggs, M.D., President, in the Chair.

A New Method of Rapidly Staining Bacilli in Sections of Tissues.—Dr. J. M. Byron presented slides and cover-glasses illustrating a new method of staining bacteria in sections of tissues. Its peculiar feature was the rapidity with which the preparation could be made, and the ease with which the sections could be made to adhere firmly to the cover-glass. This was effected by immersion of the sections in an albuminous fluid, and then coagulating the albumin.

The sections, after being well rinsed in water, were put into a solution of equal parts of a two per cent. egg albumin solution and a concentrated solution of boracic acid, the latter being added in order to preserve the albumin. When thoroughly soaked with this solution, the sections are transferred to a cover-glass, immediately dried with blotting-paper, and then immersed in a solution which will coagulate the albumin, *i.e.*, absolute alcohol, or better, equal parts of alcohol and ether, or still better, in a one per cent. solution of bichloride of mercury in absolute alcohol. These agents quickly harden and fix the sections to the glass, so that it is afterward almost impossible to separate them from it. After washing with water, they are stained by any of the ordinary methods. By the employment of this method, the speaker had been able to stain tubercle bacilli in the tissues as quickly as in sputum.

Rupture of the Vagina and Uterus.—Dr. A. T. Weston presented the pelvic organs removed from a woman who had died twenty-four hours after delivery. She had at

first been attended by a midwife, and subsequently by a physician, who was unable to deliver the child by forceps or by version, and only finally succeeded by the application of the forceps to the after-coming head. At the autopsy, a laceration was found which extended up through the right side of the cervix and vaginal fornix into the body of the uterus, opening widely the peritoneal cavity. A large quantity of fluid and clotted blood was found in the abdominal cavity. The hand could be easily passed from the vagina through the rupture into the peritoneum.

Fatal Peritonitis from Necrosis of the Uterus.—Dr. Weston presented specimens from another case of sudden death after confinement. Immediately after delivery, the woman had done so well that she was out of bed on the fourth day. About the ninth day, she suddenly developed a septic peritonitis, and died twenty-four hours later. The autopsy showed a general septic peritonitis, with diphtheritic endometritis. There was a small dermoid cyst of the left ovary.

Gangrene of the Uterus.—Dr. Weston also presented a specimen of gangrene of the uterus, which was removed from a woman who died about four days after a premature birth, but just at what period of pregnancy could not be ascertained. It was evidently a case of instrumental abortion, induced probably by the patient or some friend. The specimen showed a well-defined area of gangrene, one and a half inch in diameter, at the fundus of the uterus on the left side, and two openings through the sloughing tissues into the abdominal cavity. There was a second area of gangrene in the posterior wall about the same size as the first, extending through the uterine wall. There was a general septic peritonitis. There were also two spots of gangrene in the cervix, extending entirely through the muscular portion to the peritoneum, but not involving it.

These three cases had all come under his observation in less than a week.

The President said that these cases usually gave a history of mechanical interference with delivery, and of secondary infection, followed by local infection and gangrene of circumscribed portions of uterine tissue, which result in establishing a direct communication between the cavity of the uterus and the abdominal cavity. He had only seen one other case of gangrene of the uterus, and in this one the history was much the same, and there was a circumscribed spot of gangrene in the fundus, about one inch in diameter, associated with a general septic peritonitis.

Diverticulum of the Œsophagus.—Dr. George P. Biggs presented a specimen of diverticulum of the œsophagus. It had been removed from a man about sixty years of age, who had died of acute lobar pneumonia. There was no history bearing upon the condition.

The autopsy showed the existence of extensive atheroma of all the vessels, but particularly of the aorta, where it extended from the transverse arch to the iliacs. The whole aorta was calcareous, and in spots it was ulcerated, but there were no signs of aneurismal dilatation, and the degenerative process seemed to be confined to the intima. The diverticulum was situated about one and a half inch below the bifurcation of the trachea, and extended backward toward the spinal column. The posterior portion was accidentally cut off in removing the aorta. The opening of the diverticulum measured 2 ctm. by 1 ctm., and the diverticulum itself 4 ctm. by 2½ ctm. There were no evidences of inflammation.

An Echinococcus Cyst of the Liver.—Dr. Biggs also presented a specimen of this condition. It was found in a man about sixty-two years of age, who had died of acute lobar pneumonia. There was no history indicating the existence of such a condition. In the free border of the left lobe of the liver was a perfectly round, calcareous body, 1½ ctm. in diameter, and at the junction of the right and left lobes was a mass, 4 ctm. in diameter, projecting from the free border. The latter had a firm external capsule, and on section was found to contain pultaceous material. Microscopical examination showed the presence of the characteristic hooklets of the echinococcus, and the laminated layers of the old cyst-wall, together with much granular material and some cholesterine crystals. In the sac-wall were a few heads of echinococci clinging to it, but the cysts had apparently disappeared.

The President presented the left hemisphere of a brain removed from a man, thirty-four years of age, who had been an inmate of the almshouse for a number of years. There was some paresis of the left side, and complete paralysis of the right, with secondary contractures. His power of speech was quite limited, although he could swear with vigor and fluency, but he could read and write, although when writing there was a good deal of muscular twitching. He died from *la grippe*. At the autopsy, the left hemisphere was found to contain a large area of atrophy, which involved the posterior portion of the first, and a part of the second, frontal convolution, the lower portion of the anterior and the posterior central convolution, with a part also of the first temporo-sphenoidal. Over this area, as is usual in these cases, there was a kind of cyst formation, the outer wall of which was formed by thickened pia, and the internal and lateral walls by sclerotic brain-tissue. On the right side there was a good deal of dilatation of the ventricle, and some smaller areas of atrophy in the cortex. The specimen showed extremely well the sort of atrophies which were constantly found in the cases occurring in the almshouse, but it was unusual to find them in one so young. Several of the superior branches of the left middle cerebral artery were extremely small, and the walls were very much thickened, some of those vessels supplying the area of atrophy seeming to be nothing more than fibrous cords. He thought the condition was due to thrombosis, or obliterating endarteritis with thrombosis, but it might have resulted from hemorrhage. The facility that this patient showed in swearing was an interesting confirmation of the claim made, that there were centres on both sides for this faculty.

Gunshot Wound of the Brain.—The President also presented sections of the brain removed from a man, aged thirty-seven, who had attempted suicide by shooting himself. The ball, which was of large calibre, entered the brain on the right side, just in front of the apex of the temporo-sphenoidal lobe in the third frontal convolution. It passed almost transversely, but a little downward and backward, through the anterior part of the brain. The track of the bullet lay above the lateral ventricle on each side, and passed through the great longitudinal fissure, above the corpus callosum, and strangely enough, did not pass completely through the left frontal lobe, but lodged about half an inch from the surface of the cortex.

It was interesting to note that the man lived six weeks after this injury. The case occurred in the service of Dr. Charles Phelps, at St. Vincent's Hospital, and was operated upon by him. The patient was first trephined, and considerable depressed bone elevated, but the bullet was not found. He recovered from this operation, and gained a moderate amount of mental power, but he was constantly lethargic. There was scarcely any elevation of temperature for two or three weeks, and only very slight paresis on the left side. He was able to be up most of the time. After the third or fourth week he developed more pronounced cerebral symptoms, with elevation of temperature. A second operation was performed, and considerable pus and broken-down brain-matter was evacuated. The patient improved temporarily after this operation, so that he was able to get out of bed again, but he gradually failed in strength until the time of his death; but at no time did he develop any marked paralysis.

The specimen of the brain presented was divided into sections, and showed very clearly the track of the bullet.

At the site of the wound there was considerable loss of brain-tissue. After the bullet had passed through the longitudinal fissure to the left side, it had evidently cut through a blood-vessel, for there was considerable hemorrhage, and more destruction of brain-tissue.

The President said that Dr. Van Gieson had requested him to report that the tumor presented by Dr. Sachs at the last meeting, and referred to the Microscopical Committee for examination, had been found to be a specimen of tuberculosis of the brain.

The Society then went into executive session.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE CONDITIONS OF THE CURE OF CONSUMPTION—ACTINOMYCOSIS—DR. BURDON SANDERSON ON THE NATURE OF THE PROCESS OF INFLAMMATION—DEATH OF MR. WHARTON JONES, F.R.S.

LONDON, November 14, 1891.

"The Conditions of the Cure of Consumption" formed the subject of a communication, by Dr. Burney Yeo, to the Medical Society of London at its last meeting. Dr. Yeo pointed out that while many competent observers regarded phthisis as curable, this belief was based upon the fact that traces were found in many cases, post-mortem, of tubercular lesions which had undergone spontaneous cure. Thus Bronardel, basing his conclusions on the results of post-mortem examinations on persons who had died violent deaths, asserted that sixty per cent. of persons over thirty years of age had been the subjects of tuberculous disease of the lungs which had undergone spontaneous cure. It was, however, necessary to distinguish between localized tuberculous lesions in the lungs and phthisis properly so called; the former were indisputably curable, but the latter was much less so. Grancher held that the tuberculous patient "who had become phthisical" was incurable, and Dr. Yeo admitted that in most cases of phthisis the conditions favorable to and admitting of a cure had passed away. Early diagnosis was important, and, therefore, the early occurrence of hæmoptysis was favorable, for it served to excite the attention of the patient to his condition. The author summed up the therapeutical indications as follows: 1, Abundance of suitable food; 2, residence in a dry, aseptic atmosphere (in the country or by the seaside) of equable temperature, but not necessarily cold, with plenty of sunlight; 3, counter-irritation; 4, internal medication. As to the latter, he mentioned specially creosote and the hypophosphites; the latter gave the best results in the young and in patients of light skin and sanguine temperament. He had observed benefit from Bergeon's treatment in some cases. No patient systematically inhaled antiseptics without marked benefit.

At the last meeting of the Medical and Chirurgical Society the evening was devoted to discussing the subject of "Actinomycosis." Dr. W. H. Ransom described a case in a man, aged fifty, in which the vermiform appendix was affected, causing perityphlitis. Dr. William B. Ransom related a case of actinomycosis of the digestive and urinary tracts in a man aged forty-eight. Mr. A. R. Anderson gave an account of a case occurring in a man, twenty-nine years of age, in whom the disease affected the face and neck. He had operated with success.

Dr. Pye-Smith said he had seen the first case several times, and he agreed with Dr. Ransom that it was probably hopeless from the first. He thought the disease was probably contracted from barley—not from flesh. It was difficult to decide the botanical position of the ray fungus, but he thought it would most likely turn out to be a fission-fungus. When situated externally it could be removed, but internally it was incapable of cure.

Professor Crookshank remarked that Mr. Anderson's case was the first successful operation on actinomycosis reported in this country. The disease was very common here, and was known to veterinary surgeons as osteosarcoma or osteofibroma; in the United States and Australia it was termed "lumpy jaw." If some of the pus was allowed to trickle down the side of a test-tube held up to the light, if it contained any of the fungus masses they could easily be recognized as small black specks. He thought that morphologically the fungus was somewhere between the fission and the higher fungi. The disease was probably caught from cereals, and not from cattle or from another man.

Dr. William Hill thought the botanical position of the fungus was among the basidiomycetes, and not among the fission-fungi; this view was supported by the fact that the fungus underwent an alternation of generations.

The way in which pathological doctrine has swung to and fro on the subject of the nature of inflammation has been well shown by Dr. Burdon Sanderson in the Croonian Lectures he is delivering at the College of Physicians on "The Progress of Discovery Relating to the Origin and Nature of Infectious Diseases." In his first lecture Dr. Sanderson maintained that the definition of inflammation which he had once given—that it is the response of living tissue to injury—still holds good, but he proceeded to point out how the doctrine of the infective nature of inflammation had originated, developed, and undergone modification. Up to 1860 it had been assumed without question that whenever inflammation occurred in consequence of an injury—whether chemical or mechanical—the *apparent* cause of the morbid process was the real one. Since that time it had, however, become gradually clear that in the majority of instances this was not so. In 1870 Mr. Simon recognized the probability that the doctrine which had a little before been set forth by Professor Halier—that specific contagia are in their essence living microphytes—was true. The next year an extensive series of researches was conducted by Dr. Klein and Dr. Sanderson, in which they observed the fact that the presence of micrococci in groups or chains, as well as rod-like microphytes, was so characteristic of all such suppurations that they had no doubt that it was to them that these products owed their infecting character. The lecturer then traced the development of the doctrine of the dependence of inflammation on microphytes. In 1880, he said, there was a new departure consisting, first, in the demonstration that in all ordinary cases of acute suppurative inflammation the purulent product contained microphytes special to it, and, secondly, in the application of the methods with which about that time Dr. Koch had enriched pathology for separating species of microphytes from each other and obtaining pure cultures. We owed the demonstration that all acute inflammatory products contain characteristic forms of microphyte to Professor Ogston, of Aberdeen. Dr. Sanderson then described in some detail the researches of Ogston, Rosenbach, Krause, Rodet, and others on staphylococcus (cluster coccus).

He referred to streptococcus (chaplet coccus) and said its action resembled staphylococcus in most respects. The fact that two microphytes which were so easily distinguishable in the laboratory—the micrococci of one being arranged in clusters, and those of the other in chains or chaplets—should be almost indistinguishable in their action, evidently bore on the view to be taken of the relation between a microphyte and its morbific action.

In his second lecture Dr. Sanderson showed that, leaving out of consideration those wholly exceptional cases in which inflammation is produced by exposure to heat and cold, and which had not yet been investigated in their relation to microphytic influence, its proximate cause was always chemical. Suppuration could be produced by chemical agents in the absence of microphytes, and when produced by microphytes the action was chemical. The chemical substances which had been experimented with

were numerous and their action varied somewhat in different animals. Mercury produced suppuration in the dog (each drop injected hypodermically becoming the centre of a minute abscess), but not in the rabbit. Nitrate of silver in five per cent. solution produced suppuration in the dog with great certainty, but not in rodents. Ammonia failed to produce pus in any animal; it was either absorbed or else it killed the tissue with which it came in contact. Of organic substances, turpentine had been most experimented with; in the carnivora it produced abscess with great certainty. The experimental proof that the action of microphytes was chemical lay in the observation that in the case of many micrococci the symptoms resulting from their presence in the living body could be produced by the injection of devitalized cultures containing the soluble chemical products of their vegetation.

By the death of Mr. Wharton Jones, F.R.S., the profession loses one of its members well known to a by-gone generation as a working physiologist. Although for years in practice as an ophthalmic surgeon, Mr. Wharton Jones's chief work was done in the domains of physiology, and particularly in regard to the physiology of the circulation. He refused to accept the theories put forward by Cohnheim, and during the last few years has from time to time engaged in controversy to point out the want of experimental proof in support of Cohnheim's views.

EXSECTION OF INTESTINE.

To the Editor of the Medical Record.

SIR: In Wood's "Reference Handbook," vol. viii., p. 300, article Hernia, I have claimed that a case of my own there recorded represented the largest amount of intestine ever successfully removed, with restoration of continuity, in a strangulated hernia, in America. The excised portion measured about thirteen inches.

This statement was upon the authority of Dr. A. J. McCosh's tables, published in the *New York Medical Journal* for March 16, 1889, and which were evidently compiled and elaborated with great care and research.

Some weeks ago I heard, indirectly, of an instance in which, it was said, a much greater length of bowel had been sacrificed, and with recovery, than in the case recorded by me. I made inquiry accordingly, in order to obtain the facts; and the subjoined letter, received to-day, is the result.

I would ask you, sir, to oblige me by publishing it, both because of its intrinsic interest and for the reason that Dr. G. D. Beebe is evidently the surgeon entitled to the credit and not myself.

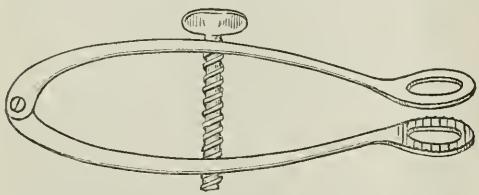
It is, of course, well known that yet greater losses of small gut have been, in a few instances, recorded by certain European surgeons than that sustained by Dr. Beebe's patient. Koeberle, for example, has resected 2.05 metres, and Kocher 1.60 metre, in each case without a fatal issue.

Very respectfully yours,
ROBERT H. M. DAWBARN, M.D.

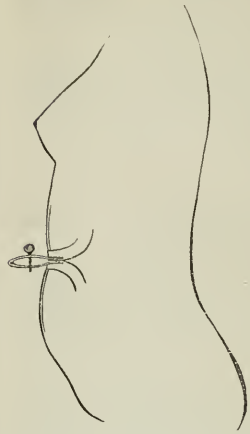
345 West Fifty-Sixth Street, November 5, 1891.

"ROBERT H. M. DAWBARN, M.D., NEW YORK.

"DEAR SIR: Replying to your note of the 29th ult., I would say that my brother, Dr. G. D. Beebe, in 1869,



operated upon a strangulated umbilical hernia in a woman (then pregnant some three or four months I believe), and, finding the strangulated gut sphacelated, he removed four feet and ten inches, stitching the ends to the abdominal wall, thus making an artificial anus. After she had recovered from this operation he made an opening through, between the two adjacent intestines, by means of a clamp, after which the external ends were refreshed and the abdominal wound was closed by quilled sutures. In due time she was delivered of her child, and may be alive to-day so far as I know. My brother died nearly fifteen years ago. I have somewhere a report of the case, published in pamphlet form soon after the operation, but have not succeeded in finding it. It was, I think, published in several medical journals and was also taken up by the newspapers and copied from one to another as far as Australia. I make on the back of this sheet a rough diagramatic drawing to show the method of restoring the continuity of the intestinal tract.



This clamp was screwed down so as to bring the adjacent intestinal walls together and produce adhesive inflammation. It was then tightened so as to cause a disk the size of the blades to slough out, thus leaving an opening from one intestine into the other. As I assisted at the operation and personally knew all the details, I can depend upon my memory, with confidence, in the matter.

"Yours very truly,
"A. G. BEEBE, M.D.

"582 West Adams Street, Chicago, Ill.
"November 2, 1891."

MEDICAL EDUCATION — FROM THE STUDENT'S POINT OF VIEW.

To the Editor of the Medical Record.

SIR: Dr. Stephen Smith, in his recent address before the New York State Medical Society, on "The Art of Teaching Medicine," made a happy use of his opportunity in calling attention to a defect in the present system of medical education that, seemingly, has not received from teachers of medicine any part of the consideration that it deserves. I am sure many medical students who have considered the inconsistencies under which they labor will agree with me in saying that in attacking the prevailing method of teaching medicine by lecture to undergraduates he has pointed out the greatest defect in the present system of medical education. And it is a hopeful sign when a man of Professor Stephen Smith's ability and conservatism, and with a long experience in teaching medicine, utilizes the distinguished position from which he speaks to emphasize the obsoleteness of our present methods of teaching medicine.

As Professor Smith tells us, there once was a time when medical lectures to students were based upon good reasons. When books were scarce and costly, and often even unobtainable by students, there was good reason for teachers dictating their lectures to their students. Even later, when one man might embody in himself an encyclopædic knowledge of medical science, teaching medicine by lecture was justifiable; and now I suppose few persons will question the value of lectures to educated medical men by men who have something original to say and who are authorities in their especial lines. But at the present time, when books are the most inconsiderable element in the cost of a medical education, and when no man can offer his students a statement of even one branch

of medical science as good as they can get in their text books, what are the reasons for lecturing upon the elementary subjects of medicine to undergraduates, and even to beginners? And that, too, in face of the fact that it is now done in no other department of scientific education.

If there are any good reasons for so doing, they must be either: 1, That medicine so taught is more thoroughly and permanently impressed upon the students than by the usual methods of scientific education; 2, or that it can be more rapidly taught; 3, or that it can be taught as well and more agreeably; 4, or that by lectures the professors can from their own stores of original knowledge give the students valuable information not to be gotten elsewhere; 5, or that lectures as supplementary to private study are of more value to medical students than recitations and the ordinary methods of teaching sciences.

One is tempted to think that the absurdity of most of these suppositions is evident in their very statement, but it may not be useless to examine them briefly in detail.

As to the first supposition, Is it true that medicine taught by lecture is thoroughly and permanently impressed upon the student's mind? Of what he succeeds in getting from his lectures, possibly it is. But how often does a student succeed in following a lecturer closely enough to make his information upon a point satisfactory or complete?

No student depends upon his memory or his notes of a lecture for a satisfactory knowledge upon a scientific question; what he must have is exact and complete information, and with the errors arising from inexact statement on the part of the lecturer, and from misunderstanding and misinterpretation upon the part of the student, every student knows that he cannot depend upon his lectures for that. What student, for example, ever succeeds in learning from a professor's lectures the functions of the medulla? To get information that will be of use to him he has to go to his room and study, not simply read with attention, the very matter that he has been lectured to about all day. In the time that he has sat and listened to lectures he could have learned thoroughly all his teachers have gotten over and more besides, and then have had his evening for other work. It is really not too much to say that for most students the professor's lectures are little more than announcements of what the student must study when he goes to his room; coupled usually with an unconscious announcement of the points upon which each professor, according to his peculiarity, lays stress, and which, therefore, the student gets up with particular attention in order to work it off "on the old man" at examinations.

The second supposition, that medicine can be rapidly taught by lecture is certainly without foundation in experience. No lecturer can intelligently cover in an hour nearly as much as a good student can learn in the same time. For example, a lecturer does remarkably well if he covers half of the subject of practical medicine in a session of six or seven months; how would a student ever get ready for his examinations if he had to wait for his lecturer?

Now in order to consider the third supposition let us for the moment grant that medicine can be taught as well by lecture; is it, then, true that it can be taught by lectures more agreeably than by ordinary methods? For the professors, perhaps, yes. It is flattering to one's self to stand as an authority before four hundred young men; to deliver one's self "oracularly;" to be received with applause; and to have men hang upon one's words—it is easy to see that these things are agreeable, incomparable to the drudgery of the quiz-masters. But for the students it is a different matter. The very physical labor of sitting for five or six hours per day in a cramped opera-chair in a crowded lecture room, the air of which soon becomes hot and bad, is in itself hard work. It is in fact so hard that, unless a student has more than ordinary energy and determination, it is about all that he can do.

And now as to the next supposition. Does anybody believe there is a necessity for medical lectures in order that the professors may give their students the benefit of their original information? Indeed, is it often that the student needs anything that is not the common property of the current medical text-books? If original information or superior arrangement of the topic were the condition of the delivery of medical lectures, how many lectures would be given in any of our schools? What teacher is there who has anything to say to his students that has not already been said by himself or somebody else in a better way in a book?

It is talking mere commonplace to say that the substance of the didactic lectures of our medical schools is simply the common stock knowledge of medical literature. What, then, is the reason for consuming the best part of a student's time in giving him that which he can get in better shape for himself in his Gray, or his Foster, or his Brunton?

If we pass to the next supposition and ask, as a supplement to private study, are not lectures of great value to the student, we get no more satisfaction. Clinical lectures are, of course, valuable supplements; but with them I am not concerned, for I take it that no one would abolish them. But as for didactic lectures. In the first place, even if didactic lectures were valuable to impress upon students the information gotten from their own study, they consume too much time to be useful for that purpose; until the day is made longer than twenty-four hours students cannot afford to spend six or seven hours of the day in having the results of their study impressed upon them. But lectures are not even a good method of doing this. At a lecture a student plays an entirely passive part; whatever interest he takes is the result of a voluntary and, with most lectures, a very earnest effort. He has no part to play in the mental exhibition; he has simply to listen and listen, and take in and take in; and the mind to do its best must have something more required of it than to note passively thoughts already elaborated by someone else.

It would be presumptuous for me to attempt to tell the best methods of teaching the sciences. These methods, at least so far as all other departments of scientific education are concerned, are already established. To make the student an active agent in the exchange of ideas between him and his teachers, to make him a part of his work, to find out what he knows and to find out what he does not know, to make him do his own thinking—these are the aims at the foundation of approved methods of education, and there are no adequate reasons why they should not as well be applied to medical education as to education in the other departments of science.

That the foregoing conclusions are true is proven beyond the point of doubt by the way in which students flock to the quiz-masters. That young men, most of whom are poor and in earnest about their work, and the best of them as well as those without determination—that these, usually at considerable pecuniary sacrifice, should go outside of their schools and eagerly grasp the aid that the quiz-masters offer them, testifies stronger than anything else could to the value of recitations and intimate association with one's teachers.

A young man, especially if he comes from a good college, finds himself about three months after he enters his medical school in a peculiar situation. He has paid tuition and other fees for a six months' course, to the amount of about two hundred dollars, and unless he is a *rara avis* that is about all he cares to pay until next October. He finds, however, that, after deducting his fee for dissecting, for work in the histological laboratory, and for a little other practical work of that sort, he has paid about one hundred and forty dollars for something that he regards as of very questionable advantage; in fact, but for its necessity in getting a diploma and license to practise medicine, he is beginning to think he is not getting much return for that hundred and forty dollars. He per-

severes, however, for a while in attending the lectures, thinking that the school certainly knows what he needs better than he does. He keeps this up for a while, until he becomes firmly convinced that he is spending his time to poor advantage. Then he sees that something must be done; he sacrifices to his necessity a hundred dollars more of his much-needed money; he takes a "quiz;" and if he is one who is not afraid to act on his convictions, he cuts his didactic lectures and begins to study. And I might follow him up, as the novelist does his hero, by saying he is a good student and finally graduates with high standing in his class; for the fact is beyond dispute that many of the men who take high places in their classes pursue the very course outlined above, and that nearly all of the men who take the best standing pursue that course to a greater or less extent. It may be objected that there are good students who graduate high in their classes who do so without taking a private "quiz;" but they are so greatly in the minority that they only render the phenomenon more striking.

If, as recently a representative of the large class of medical students, I might offer an opinion, it would be that the crying need of medical education is not a longer period of undergraduate study, but the application to medical teaching of the approved methods of instruction followed in other departments of scientific education. Judging from a five years' experience with college men and their work under favorable conditions, I am very much inclined to the opinion that medical students could, under a system where they would be allowed to apply their time to the best advantage, do a better quality of work, and as much in two years as they now do in three.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 22, 1891, to November 28, 1891.

Maus, Louis M., Captain and Assistant Surgeon. Granted leave of absence for one month.

Ball, Robert R., Captain and Assistant Surgeon. The leave of absence granted is extended one month.

Taylor, Arthur W., Captain and Assistant Surgeon. The leave of absence granted for seven days, is hereby extended twenty-three days.

Wood, Marshall W., Captain and Assistant Surgeon. Granted leave of absence for three months, with permission to apply for an extension of one month.

Hall, William R., Captain and Assistant Surgeon. Granted leave of absence for twenty days.

Official List of Changes in the Medical Corps of the United States Navy for the week ending November 28, 1891.

Guest, Middleton Semmes. Commissioned an Assistant Surgeon, November 19th.

Martin, William, Surgeon. Ordered to the Thetis.

Wilson, George B., Assistant Surgeon. Detached from the Thetis, ordered home, and granted two months leave.

Two Suicides.—Two women recently committed suicide in England. One, the wife of a laborer, chose whiskey as the agent of destruction, swallowing a pint of it at one gulp, and died in a few hours. The other, a woman of gentle breeding, swallowed a large number of morphine lozenges. And so they winged their flight, starting from different places and going by different routes, but reaching the same goal at the end.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 28, 1891.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	29	9
Scarlet fever	146	29
Cerebro-spinal meningitis	1	1
Measles	69	5
Diphtheria	112	36
Small-pox	0	0
Varicella	7	0
Pertussis	0	1
Erysipelas	1	0
Mumps	0	0
Rötheln	0	0

Cattle Disease in Russia.—In addition to the famine under which Russia is groaning, there has been serious loss sustained by reason of disease among horses and cattle which has been prevailing for several months in almost the entire country, especially in the ranches of the Crimea and the horse ranches in Caucasia. When the Veterinary Commission of the Government took notice of the fact and sent experts to destroy the infected animals, the ranchmen and the peasants of the neighborhood would not allow them to do their duty, and began to riot, which in several instances had to be put down by the bayonet. The Ministry of the Interior has therefore decided to establish a "veterinary police system" throughout the empire. The duty of the police will be to guard against the importation of sick cattle from abroad, to watch in the cattle-raising districts, the cattle markets, at the abattoirs, at the hide and leather stores, and wherever live cattle or the products of animals are sold or kept in store, that the orders of the Government veterinaries be promptly and accurately obeyed. They will have control over the dairies which furnish milk, butter, and cheese to large cities. Veterinary courts will be opened, with the power to punish the dealers in live stock and in animal products who disobey the orders of the veterinary doctors.

Medical Masons.—The Grand Lodge of Freemasons in England recently instituted the Æsculapius Lodge, composed of physicians. There has for some time been a lodge of apothecaries called the Galen Lodge.

The Duties of a Practising Physician.—It has been decided by the courts in Trinidad that a physician is obliged to respond to each and every call that is made on him for his services, whether he expects to be paid or not, and that indeed it is improper to make any arrangement about the fee beforehand. Furthermore, he must not give up a case without the consent of the patient, even though the latter is not seriously ill, and though other physicians are at near call, and if he does refuse further attendance he may become liable to heavy damages.

Dr. Edward Polak, who was for many years the physician to the Shah of Persia, died recently at the age of seventy-one years.

Of Course.—In an address before the students of Meath Hospital, Mr. Macnamara remarked that "there is a fashion in medicine as strong as, if not stronger than, that which rules in dress."

Alcoholism in Great Britain.—In 1890 there were 173,036 convictions for drunkenness in Great Britain, of which number 23,212 were in London, 10,773 in Durham, 13,154 in Lancashire, and 9,826 in Yorkshire.

Dr. Mosetig-Moorhof has recently been appointed chief of one of the surgical divisions of the Vienna General Hospital.

ESSENTIAL PAROXYSMAL TACHYCARDIA.[1]

BY JOHN WINTERS BRANNAN, M.D.,

NEW YORK.

I HAVE suggested for discussion this evening that form of tachycardia in which a very great acceleration of the pulse, occurring in paroxysms, is the cardinal symptom. The paroxysm may last a few minutes, or it may extend without interruption over a period of several weeks. In the intervals between the attacks the heart beats with normal frequency and force, and the individual seems in perfect health. There is no history of rheumatism, nor are there any valvular murmurs to be detected.

Four cases have come to autopsy. The entire nervous system was found intact in all, nor did the changes in the heart seem of any significance to those reporting the cases. All the other organs of the body were free from disease. It is a rare affection, and I have been able to find only twenty-six cases recorded in the journals. The case I am about to relate was first seen by me several years ago, and I have not yet forgotten the impression it made upon me, though it was not a very severe form of the disease.

On December 12, 1885, at 11 P.M., I was called in haste to see Mrs. L——, a woman thirty-five years of age. She seemed in great distress, and complained of palpitation and severe pain to the left of the sternum. She attributed her symptoms to her having been very much startled by her son, a weak-minded epileptic. She stated that she had had a similar attack two years previously, and from the same cause. She was a stout woman of rather nervous temperament, and had been troubled somewhat with dyspepsia. I learned later that she was two months advanced in pregnancy.

On examination I found the heart beating at the rate of two hundred pulsations to the minute, impulse strong. There were no murmurs or other adventitious sounds. The thyroid was not enlarged; there was no prominence of the eyes. I at once gave her a quarter of a grain of morphia hypodermically, and ordered a belladonna plaster to the seat of the pain, and one minim of the fluid extract of digitalis to be taken four times a day. Rest in bed was also enjoined.

December 13th.—The patient said that she had had but little sleep during the night, and had noticed that she was passing very little water. The heart's action was unchanged, but in spite of the vigorous systole the pulse was of very low tension, almost impossible to count at the wrist. The urine was examined, and proved to be normal in all respects. The patient was pale and anxious, but not suffering to any extent. I increased the digitalis to five minims in the twenty-four hours, gave her one third of a grain of morphia at night, and also a laxative pill.

December 14th, Morning.—The patient expressed herself as more comfortable. She had slept soundly and thought the palpitation was less. On examination the heart was found as before. The digitalis was continued. Evening: The heart was acting quietly, seventy two beats to the minute. There was no enlargement nor any sign of valvular lesion. I continued the digitalis in diminishing doses for several days, and put the patient on a strict dietetic regimen. She remained under my observation for some two years, and during that period she had no return of the paroxysm, in spite of the fact that she aborted at the sixth month. I have heard of her since at intervals, and know that she is still alive and in good health.

I was inclined at the time, from lack of any other diagnosis, to regard this case as simply one of unusually severe reflex palpitation, due perhaps to gastric derangement in a pregnant woman of nervous temperament, the fright serving as an exciting cause. About a year ago, however, my attention was attracted by an article entitled "Essential Paroxysmal Tachycardia," by Bouveret,[1] of Lyons. It is an exhaustive study of the subject, based upon two cases seen by himself, and nine others reported by Bristowe,[2] Proebsting,[3] Pribram,[4] Huppert,[5] Bensel,[6] and Winternitz.[7] Bouveret was the first to give the affection a distinct name and place among the neuroses, and in this he has been followed by most of the French and German observers. In addition to the writers mentioned above, Gerhardt,[8] Brieger,[9] and Fraentzel,[10] in Germany; Sollier,[11] Huchard,[12] Debove,[13] Faisans,[14] Rendu,[15] and Perrin,[16] in France; and H. C. Wood,[17] of Philadelphia, have reported cases. I have excluded all those cases in which there was a history of rheumatism, or in which valvular murmurs or other signs of cardiac disease were noted. In all I have found twenty-seven cases, including my own, which correspond to the picture given by Bouveret of the disease.

In his description of the paroxysms Bouveret divides them into two classes, according to their greater or less duration, because of the pathological consequences which ensue if they are prolonged beyond a certain period. If they last more than four or five days, we see secondary disturbances of the circulation and respiration, due to the rapid weakening of the heart, its dilatation, and the incomplete emptying of its cavities.

In the short attack there is nothing noteworthy except the extreme rapidity of the heart's action. This rapidity may attain 250 or even 300 pulsations a minute. It is very like that produced by section of the pneumogastrics in animals. The pulse is usually regular; occasionally there are periods of irregularity. It is often not perceptible at the wrist, but is to be felt in the carotids and femorals. The second pulmonic sound is accentuated, showing increased tension in the pulmonary artery.

Sometimes there are prodromata, such as dizziness, or a sense of constriction at the throat or epigastrium. Generally the beginning is sudden, without warning. Often there is no cause for the attack, at other times it follows some strong mental emotion or physical fatigue

or effort, and such causes are especially efficient during convalescence from a previous attack. The face is usually very pale throughout the paroxysm. The pupils are normal, and there are, as a rule, no vaso-motor disturbances.

There may be moderate dyspnœa; anorexia and constipation are usually present, and almost complete insomnia. There is marked diminution of the urinary secretion, but no albuminuria and no fever. In some cases the temperature is below normal.

The subjective sensations are variable; sometimes epigastric oppression, pain at the præcordia, numbness of the left arm, or general chilliness.

The attack ends as abruptly as it began, the pulse dropping suddenly from 200 or more to 72 beats a minute. Huppert noted the change of the pulse in his patient from a vague undulation to strong, regular, slow, equal pulsations. The short attack leaves but little prostration afterward.

The long paroxysm, however, is much more serious, because of the secondary respiratory and circulatory disturbances.

There is extreme cardiac distention, as shown by the dulness. In one case of Bouveret's the dulness extended from the upper border of the third rib to two inches below and outside of the nipple, and from an inch to the right of the sternum to one-half inch beyond the left mammary line.

Sometimes there is a soft systolic murmur during the paroxysm or during the convalescence, disappearing later. The stasis in the left ventricle and auricle and pulmonary veins causes congestion and œdema of the lungs.

The patient has cough, dyspnœa, and bloody expectoration. Sonorous and sibilant râles and friction-sounds are to be heard. In some cases there is pleurisy with effusion. The temperature may rise three or four degrees, owing to the pulmonic process.

There is marked cyanosis of lips and cheeks, and swelling and pulsation of the jugulars.

There may be agitation and restlessness at night, unpleasant dreams, and even delirium.

The cerebral disturbances are probably due to the arterial ischæmia and venous stasis prolonged for several days.

Swelling of the liver and spleen is noted, also ascites and œdema of the ankles. The urine is diminished and high-colored, and usually contains albumin and blood-globules. When the attack ceases the urine increases in amount, and the albumin and blood disappear.

In place of the constipation of the short paroxysm there is diarrhœa as a result of the venous stasis in the intestinal mucous membrane.

The subjective sensations are usually the same as in the short attack.

In one case, toward the end of a paroxysm which had lasted three weeks, and which terminated fatally, the præcordial pain was so intense as to recall that of angina pectoris. Bouveret attributes this pain to the ischæmia of the heart-muscle, due to the same lack of tension in the coronary arteries that is found in the peripheral vessels.

Some patients have fainting spells and syncope, especially if they attempt to rise from the recumbent position.

At the end of the paroxysm the secondary symptoms disappear gradually. Several days elapse before the lungs clear up. The urinary symptoms cease at once. The heart remains irritable during the first few days of convalescence, and a return of the paroxysm may be produced by a very slight cause, such as sitting up in bed. The extreme cardiac distention, however, disappears in a few hours.

The paroxysms ended fatally in 8 of the 27 cases, twice by syncope, twice by asystolic collapse, and in the other cases by pulmonary congestion or intestinal hemorrhage.

Etiology. — In discussing the etiology of the disease Bouveret draws attention to the entire absence of hysteria or neurasthenia in the cases collected by him, nor was there any hereditary neurotic tendency. In most of the other cases reported it is also stated that there was no evidence of nervous predisposition.

Faisan's two cases, however, were those of mother and daughter. My patient was of nervous temperament and had an epileptic son.

The disease is not often observed in children. In Brieger's case the paroxysms began when the patient was nine years old. In the other cases the age at onset varied from nineteen to fifty-two years.

The influence of sex is not marked; of 25 cases in which the sex is noted 11 were males and 14 females.

Over-fatigue, either mental or physical, seems to be the chief cause of the affection. Excessive smoking is also an important factor, and the drinking of strong coffee. In Gerhardt's case the attacks came on after long-continued literary work and immoderate smoking. Bouveret's first patient, a professor, was accustomed to read and study late at night, smoking at the same time. He also drank considerable coffee.

In one case the paroxysm was caused by a fright two or three days after confinement. In my patient a fright seemed to be the exciting cause. In Sollier's case the attacks occurred whenever the patient, a lace-maker, had been greatly vexed or annoyed in her business.

Pathology. — The pathology of essential paroxysmal tachycardia is still undetermined, and is perhaps not the same in all cases. The majority of observers believe that we have to do with a pure neurosis, a temporary disturbance of the motor innervation of the heart. Such a disturbance might be caused in three ways: by excitation of the sympathetic, by a modification of the activity of the intra cardiac ganglia, or by a temporary paresis of the vagus. Dr. Wood considers the tachycardia to be due to a discharge of nerve force and not to a paralysis of inhibition, comparing it to the epileptic paroxysm, which, he holds, is the result of a discharging lesion, and not of a temporary palsy.

The tachycardiac paroxysm, in his opinion, is likewise due to a discharging lesion affecting the centres of the accelerator nerve of the heart, the sympathetic.

Nothnagel,[1] on the other hand, employs the same illustration to support the theory of a paresis of the vagus. He sees in the loss of consciousness which accompanies the epileptic convulsion a sudden spontaneous cessation of functional activity on the part of central nervous organs, a sort of torpor or temporary paralysis. In the same manner we can conceive, he thinks, of a temporary torpor of the cardiac centres of the vagus in the medulla. The respiratory and gastric centres are not affected, nor is the trunk of the nerve itself.

It has already been stated, in the description of the paroxysms, that there are, as a rule, no vaso-motor symptoms nor changes in the pupils. This fact is opposed to the idea of sympathetic irritation. What part is borne by the intra-cardiac ganglia in the nervous disturbance it is difficult to say. It is not thought that they are ever the primary cause of the attacks.

It seems probable, on a review of all the evidence, that in most cases there is a paresis of the vagus, of central origin.

In three cases there was evidently excitation of the sympathetic, as shown by the accompanying vaso-motor phenomena.

It has been proved that only a very strong excitation can overcome the vagus tone, and hence inferred that the sympathetic cannot excite a very rapid action of the heart. The few cases in which it has caused marked tachycardia are to be explained by the fact that the vagus grows exhausted by prolonged sympathetic irritation, so that finally only the cardiac motors are active.

The general conclusion, is, then, that the affection is a bulbar neurosis, confined to the cardiac centres of the vagus in the medulla.

[1] Wiener Med. Blätter, 1887, Nos. 1 and 3.

Dr. Samuel West,[1] however, does not concur in this opinion.

While agreeing that the tachycardia is of nervous origin, he believes that the nervous irritability is due to organic disease of the heart, probably of the myocardium. He suggests that there is perhaps a chronic interstitial myocarditis, developing either spontaneously or consequent in some cases on past rheumatic pericarditis, or in others on syphilis, being thus related to fibroid disease of the heart.

Let us see how Dr. West's theory is borne out by the four autopsies of which we have record. I have already stated that the nervous system was normal throughout.

In Sollier's case the heart also was pronounced free from disease, but unfortunately the myocardium was not examined. Hence this case is of no value on this point.

Bristowe states that in his case, also, the heart was normal in all respects, the muscular tissue included. But the autopsy was made four days after death, and the heart was in an advanced state of decomposition. We can hardly, therefore, attach much weight to the evidence yielded by the microscope.

We have left the cases of Brieger and Fraentzel, in both of which a careful examination of all the organs was made soon after death. The records of the autopsies are strikingly alike in the two cases, for in both there was an extensive development of fibrous tissue in the wall of the left ventricle, whereas the valves of the heart were absolutely normal. Brieger attributes the tachycardia in his case to vagus paresis combined with sympathetic irritation, and apparently attaches little importance to the post-mortem appearances. He expressly states that in his opinion the degenerative changes in the heart were of recent date and due to the long-continued irritation of the cardiac muscle. As the paroxysms had existed for twenty-four years in his case, such an explanation is at least plausible.

Fraentzel's patient, however, had suffered from tachycardia for only three months before death, and yet the changes in the heart-muscle were most marked, as will be seen from the following extract from the report of the autopsy: "Left ventricle hypertrophied; increase of connective tissue, thickest next to the endocardium; papillary muscles and trabeculæ in left ventricle very thin and everywhere infiltrated with newly formed connective tissue; foci of fatty degeneration in the connective-tissue formation immediately beneath the endocardium of the ventricular septum; entire endocardium of left ventricle much thickened, many trabeculæ have undergone fibroid degeneration."

Fraentzel makes no comment whatever upon the findings of the autopsy, but simply states, in concluding his paper, that the pathology of the disease is still very obscure.

It seems, then, that interstitial myocarditis was present in the only cases in which the muscular tissue of the heart was properly examined, thus confirming Dr. West's opinion that we should look to the myocardium for the cause of the nervous irritation. But if it is proved that there is organic heart disease in some cases at least, why need we longer say that the tachycardia is of nervous origin?

Physiology has demonstrated that rhythmical contraction is a property inherent in the myocardium and not absolutely dependent on the nervous system. It is not necessary, therefore, in all cases to appeal to a disturbance of the cardiac ganglia or nerves to explain disturbances of the cardiac rhythm. A simple lesion of the cardiac muscle is capable of producing by itself all the symptoms of disturbed rhythm. We shall see later that the paroxysms in several cases were arrested by pressure upon the cervical pneumogastric. The fact that the intra-cardiac ganglia received and responded to this artificial stimulus is proof of their integrity, in those cases at least.

[1] Lancet, 1890, vol. i., p. 641.

The pathological evidence, as far as it goes, supports the theory that we are dealing with a cardiac and not a nervous disease, but the next autopsy may demolish this theory completely.

It may be said also with truth that the clinical picture of the milder forms of tachycardia accords better with the assumption of a neurotic disturbance of the heart than with the presence of so formidable a disease as myocarditis. In some cases the symptoms are absent for years, or may disappear apparently forever.

But, in answer to this, we have the authority of Fagge[1] that fibroid disease of the heart sometimes gives rise to no symptoms whatever. Huchard,[2] also, states that sometimes at autopsies extensive disease of the cardiac muscular fibres is found, which during life had caused no marked symptoms. In other cases apparently insignificant lesions had caused grave symptoms. These discrepancies he explains by the existence in the heart, as in the brain, of regions that are tolerant or indifferent in regard to destructive lesions, and of other intolerant regions, the latter depending on the importance and the absence of anastomosis with an obliterated artery, and also depending on the function of the affected muscular fibres.

The intolerant regions are especially the papillary muscles and the fibres in contact with the ganglia and the interventricular septum—particularly the last, because on it depends the harmonious working of the two ventricles. This explanation of Huchard accords with the post-mortem appearances in Fraentzel's case. For, as you may remember, the papillary muscles and the ventricular septum were both involved in the degenerative process, thus accounting for the rapidly fatal ending.

Perhaps in the milder cases, with infrequent paroxysms, the interstitial growth is situated in the more tolerant regions of the heart muscle.

However, as I have already intimated, two autopsies do not furnish a very secure foundation for a new theory, and it is probably wiser for the present to agree with Fraentzel that the pathology of the affection is still very obscure.

Diagnosis.—A well-marked case of essential paroxysmal tachycardia can hardly be mistaken for any other disease. There is no exophthalmos nor any enlargement of the thyroid; in Graves's disease, also, the acceleration of the heart's action is continuous, and never attains two hundred beats a minute, and the pulse is always perceptible at the wrist.

Organic lesions of the vagus cause permanent tachycardia; they are accompanied, too, by respiratory and gastric disturbances. The disease does not last long, being soon fatal. Lesions of the pons or medulla would also give a constant acceleration of the pulse and be attended with motor or sensory disturbances, and very soon cause death. Angina pectoris is excluded by the absence of the intense pain characteristic of that disease. In angina, also, the pulse does not attain such rapidity.

Reflex tachycardia is more difficult to exclude, if there are present any gastric, uterine, or ovarian disturbances at the beginning of the paroxysm. In the cases referred to above, the attacks occurred at a time when all the functions of the body were in perfect order. As to whether, in a given case, the symptoms are due to a paralysis of the vagus or to an excitation of the sympathetic, that is, as Fraenkel[3] has said, only a matter of theoretical interest. Nothnagel gives the following points of differential diagnosis: If the pulse-rate is very rapid, but the rhythm is even and regular; if the heart impulse is weak and there are no other symptoms except such as are secondary to incomplete emptying of the heart, and if, finally, there is noted a paresis of other nerve-tracts running in the vagus, then we may assume a paralysis of the vagus. But when

[2] Journal de Méd. de Bordeaux, 1889, May 26 and June 2, reviewed by Whittier, Annual of Univ. Med. Sciences, 1890, vol. i., Section B, p. 43.

[3] Charité Annalen, 1878, Jahrgang v., p. 273.

the heart impulse is strong, and the peripheral arteries are well filled and firm, or when there are present other symptoms of irritation on the part of vaso-motor nerve-tracts, then there is evidently an excitation of the excito-motor cardiac nerves.

Fraentzel suggests that in addition to the above rules the effect of our therapeutic measures will also aid in diagnosis. If morphine quiets the attack, it must be due to a condition of excitement, but if there is paresis of the vagus then digitalis in moderate doses will allay the paroxysm. In many cases, however, both morphine and digitalis are without effect.

Prognosis.—The prognosis of the disease is very doubtful, especially at the beginning of a paroxysm. The unfavorable factors are—a tendency to syncope, extensive pulmonary congestion, great præcordial pain, and the unstable condition of the heart at the end of a long attack.

Of the 27 cases under consideration 8 died, 2 or 3 were apparently cured, and the others remained always liable to attacks, with possible termination in collapse, syncope, or fatal pulmonary congestion.

Dr. Wood, however, takes a more hopeful view of the affection. He believes that it has no tendency to shorten life or to develop organic disease. His patient was still living at the age of eighty seven, though he had been subject to the attacks from his thirty-seventh year. But the disease was evidently of a very mild form in his case, as the paroxysms were of short duration, never exceeding twenty-six hours. We have already seen that the dangerous secondary complications do not develop in such short attacks.

Treatment.—In the treatment of essential paroxysmal tachycardia we have to consider, first, the management of the paroxysms themselves, and second, that of the intervening periods, with a view to prevent their recurrence.

During the paroxysm the patient should rest in bed, as syncope is always a possible accident. All movement and exciting emotions should be avoided. The patient should not get up too soon after a long attack. Great caution should be exercised in examining the heart; in two cases percussion of the præcordia caused the return of a paroxysm.

The medicinal treatment is not very satisfactory. Digitalis is efficient in some cases, but fails entirely in others. Morphine may arrest the attack when it is due simply to excitation of the sympathetic.

I could not see that either drug had the slightest influence on the heart-rate in my case. Perhaps larger doses might have been more effectual. Morphine is probably always of some service, as it calms the patient and makes him more comfortable.

Caffeine, nitrite of amyl, and nitro-glycerine are all of no use. Ergotine would seem to be indicated, but has not been tried, so far as I know.

Blood-letting may relieve the condition of venous stasis that occurs in the long attacks. In two cases leeches applied to the præcordial region caused marked improvement, though both of the patients eventually died.

One patient was able to delay the paroxysm by taking a deep inspiration and then suspending breathing as long as possible. Nothnagel thinks that a deep inspiration exerts a strong stimulus on the pulmonary fibres of the pneumogastric. This stimulus, transmitted to the medulla, excites the activity of the inhibitory cardiac centres.

Dr. Wood's patient could arrest the paroxysms by swallowing cold water or hot coffee. This, in his opinion, is an argument against the probability of the rapid pulse being due to pneumogastric paralysis, since Meltzer has shown that swallowing is attended with loss of tone in the vagus centre, and consequent weakening of the cardiac inhibition. But Dr. Wood proceeds to answer his own argument by saying: "It is, however, probable that the arrest of the tachycardiac paroxysms by the swallowing of hot or cold liquids is due to stimulation of the inhibitory cardiac centre, produced by irritation of the peripheral nerve-filaments of the stomach." This explanation is probably the true one, as his patient had learned by experience that the best method was to swallow the water as rapidly as possible, and as cold or as hot as he could take it; if the water was only moderately cold, much larger quantities of it were required.

Compression of the vagus in the neck, at the level of the thyroid cartilage, was successful in slowing the heart in several cases. In one of these cases the carotids were also compressed and the patient fainted. Afterward the carotids were avoided, the pressure being applied behind them, and the attacks were arrested. Brieger tried this method in his case and was able to reduce the pulse from two hundred and fifty beats to eighty in the minute. The effect, however, was only temporary, during the continuance of the pressure. Pressure in the right ovarian region also slowed the pulse, causing at the same time marked cyanosis.

The occurrence of icterus was without effect on the pulse in his case. In Röhrig's patient,[1] however, who suffered from tachycardia associated with aortic disease, the development of icterus twice reduced the pulse from two hundred and twenty to forty beats, the pulse rising each time upon the disappearance of the icterus. This experience has suggested the use of the biliary salts in cases of paresis of the whole inhibitory system when digitalis is without effect. They are believed to act by depressing the motor centres in the heart. Choleinate of sodium, prepared from ox-gall, has been recommended for this purpose by Gerhardt, who has used it with good effect in Graves's disease.

Electricity is sometimes of service, one pole being applied to the back of the neck, the other to the trunk of the vagus or to the præcordia.

In endeavoring to prevent the recurrence of the paroxysm our chief reliance is in hygienic measures. The patient should avoid all over-exertion, whether of mind or body. He should entirely abandon the use of tea, coffee, alcohol, and tobacco, or at least use them only in great moderation. The digestion should be carefully looked after, and iron given in case there is anæmia.

54 West Eleventh Street.

SYRINGOMYELIA.[2]

By L. WEHLAU, M.D.,

SCRANTON, PA.

I PRESENT you this case this evening both on account of its extreme rarity, especially in this country, and because of the almost pathognomonic character of the symptoms the patient presents. As you all know, syringomyelia has not been observed many times in the United States. Upson, writing in 1889, Wood's "Reference Handbook of the Medical Sciences," vol. v., gives but one case, that observed by Dr. M. Allen Starr, in 1888, and Sajous's *Annual of Medical Science* for 1890 mentions only a doubtful case of Upson, and cases of Van Gieson, Church, and Hawley. In 1890 J. C. Shaw presented a case before the Academy of Medicine, New York City. In Europe the disease seems to be more common, and Schultze believes it to be as frequent as multiple cerebrospinal sclerosis. The history and present condition of my patient is as follows: J. H——, fifty-three years of age, a boiler-maker by trade, complains of burning, painful sensations over the nape of the neck, over and between the scapulæ, shoulders, and arms. The burning infrequently gives place to cutting, drawing pains, or to numbness and tingling. These sensations are not confined to the course of certain nerves, but extend over large areas, a whole limb, for instance, irrespective of nervous supply.

His suffering is often so intense as to disturb his sleep

[1] Arch. f. Heilkunde, Jahrgang iv., p. 407.

[2] Read at the May meeting of the Lackawanna County, Pa., Medical Society.

and interfere with his work. Sometimes he has a cramp-like feeling in the forearms and hands, especially in the left hand, and pressure over the cervical and dorsal spinal processes causes pain. Besides sensory symptoms he complains of loss of power in the upper extremities, and you see that all the muscles connecting the arms with the trunk, also the muscles of the upper arms, are much atrophied. Both forearms look well preserved, but their wasting is plainly shown by the difference in their circumference. One inch below the elbow the right measures $10\frac{1}{8}$ inches; the left, $10\frac{3}{8}$ inches. The wasting of the muscles of the hand, especially the interossei, gives to the fingers that position best known as "main en griffe," which condition is shown in the patient. On account of the great atrophy of so many muscles his strength has decreased, the dynamometer showing right hand but 25; left, 31. Fibrillary twitching in the wasted muscles is absent. The same process of atrophy is present in other muscles of the trunk, the glutei, and in the lower extremities, but to a less degree, the circumference of the right calf being $12\frac{7}{8}$ inches, and of the left, $12\frac{1}{8}$ inches. In regard to the deep reflexes, I may state that the reflexes of the wrist and tricipites are gone on both sides. The knee reflexes are exaggerated, especially on the left side, with slight indications of ankle clonus. On account of the objections of the patient to electrical examination, a feeling of weakness and a cramp-like feeling being complained of after the first *séance*, it was dispensed with before any satisfactory result was obtained. In examining the cutaneous sensibility, marked impairment of the sense of temperature, pain, and to some degree of tactile impression, becomes manifest. Tactile impressions are poorly conducted by the hands and by the soles of the feet, *i.e.*, the stereognostic and tactile sense of the hands is impaired to such an extent that he is not able to recognize with eyes closed a coin or bunch of keys. I may remark that this condition is an exception to the rule, the tactile sense generally remaining intact in these cases, though authors agree that it becomes or may become impaired in well-advanced cases. Sensations from some points of the extremities are not perceived and responded to as quickly as they should, giving the phenomenon of delayed sensation. The algesic sense, and the ability to distinguish between heat and cold, is much blunted over the whole surface of the body, from the hips upward, on the hands, abdomen, thorax, face, neck, and arms. Water, near the boiling-point, is felt to be warm only, no painful impression being felt. Needle-pricks on various parts of the body are felt as tactile impressions only, causing no pain. Almost the same condition is found in the lower extremities, but not quite to such an extent. The same degree of analgesia and thermal anæsthesia can be demonstrated in the oral cavity, on the tongue, lips, and inside the nose. The conjunctival reflex is preserved; a point above the exit of the right supra-orbital nerve, of the size of a dollar, responds a little better to painful and thermal impressions. The muscular sense does not seem to be much involved by the disease, though there exists a slight uncertainty in carrying the finger to the tip of the nose with closed eyes. He stands firmly with eyes closed, in spite of the diminished tactile sensibility of the soles of the feet.

In talking with my patient I have to speak loudly, and a long conversation is rather tiresome. An examination of the membrana tympani gives no clue to the deafness; for the membranes are in as good a condition as can be expected in a man of his age, although a little retracted, perhaps.

R. H. D. Contact O.)—(B. C. absent. A. C. diminished.
L. H. D. $\frac{c}{10}$)—(B. C. absent. A. C. diminished.

These facts point to nervous deafness, and in this case to an affection of the nuclei of the eighth nerve at the bottom of the fourth ventricle. In regard to the functions of the other cranial nerves, the analgesia and thermo anæsthesia in the trigeminal region have been noticed already. After having described the symptoms connected with the motor and sensory spheres, let me turn your attention to the condition of the hands. On both you find the first phalangeal joint of the middle finger thickened, flexed, and anchylosed. The left middle-finger you notice also appears shortened, as the result of a dislocation of the second phalanx upon the palmar side of the first phalanx. The distal phalanx of the ring-finger is bent and points toward the ulnar aspect of the hand. On the phalangeal joints of all the fingers there are to be found either the marks of old ulcers or small recent ones; these affect only the skin. They are more prominent at present on the dorsal aspect of the phalangeal joints of the left index-, middle-, and ring-fingers. On the dorsal side of the second phalangeal joint of the left middle-finger there exists a warty, horny condition, apparently springing from the bottom of an old ulcer. These ulcers look at first like little blisters about the size of a pea or bean, the skin ruptures, and the ulcer forms, leaving afterward a smooth, depressed cicatrix.

Under the head of vaso-motor and secretory changes we notice that the patient says that he sweats very profusely on the face, very little on the body, and that his mouth is generally dry from lack of saliva. His poor appetite may be due to secretory changes of the stomachical glands; the bowels are constipated, and the bladder is emptied with difficulty.

These last two symptoms point to a deficient expulsive action of the bladder and rectum. Finally, I may mention a slight dorsal scoliosis, convexity to the right.

After having given you the history of my patient, I beg you to listen to the description of another case, taken at random from a series of five cases observed in the Heidelberg Klinik, published by Johann Hoffman in one of Volkmann's clinical lectures for April, 1891.

Mrs. E. H——, aged thirty-nine, married; cannot give any cause for her present condition; comes from a healthy family, has two healthy children; five years ago had a mild attack of diphtheria; three years ago she complained of a feeling of soreness and tension in the left shoulder, less when at work. At the same time she acquired a felon on the right index-finger, and deep cracks formed at the palmar side of the finger-joints, which gave but little pain. During the last two years she has noticed her left arm and hand becoming weak, and has felt fibrillary twitching in the small muscles of the hand. These fibrillary contractions became worse in cold weather, and often did not permit her to do needle-work. The left arm felt always cold, became blue in cold weather, and did not perspire as much as the right arm and feet. Since that time she has also been unable to distinguish hot and cold water with the left hand, and often burns her hand without being conscious of it. She still has tactile sensations, but they are not as acute as before. Like the left arm, the left occipital region also showed sensory alterations, it felt different from the right when she combed her hair. Fifteen months ago she suffered painless panaritia of all the last phalanges on the left hand, and a bulbous eruption appeared in the palm, healing very slowly. Also the right hand, she observed, was not as good as formerly, the fingers trembled much, and the right palm became more hollow and deep. On New-Year's day, 1889, she had an attack of influenza, with temporary difficulty in hearing and hyposmia. In February of this year she suffered from violent burning and biting pains in left shoulder and scapula. After using liniment without relief she applied a hot sand-bag, which made her feel more comfortable. In the evening, when her husband intended to rub her again with liniment, he found the whole region burned and the skin destroyed, the patient not having experienced any sensation from scorching. She has noticed during the last eight weeks that her legs tremble and shake, and she has a feeling of soreness and tension in the left calf, and peculiar sensations in the left thigh. She complains of great nervousness, and at the slightest provocation her legs commence to shake and twitch. Her general health is good, and

there are no psychical nor cerebral symptoms present. The woman gives the impression of a strong and robust person.

Looking at her face, a slight narrowing of the palpebral fissure, not due to paresis of the orbicularis or levator palpebrarum, but to a lesion of the cilio-spinal centre, could be seen. Examination of her back revealed a granulating surface of the size of a hand, the result of the application of the hot sand-bag. This granulating surface was healthy-looking. There was no kyphosis nor scoliosis, but the spinal column was somewhat tender to pressure in the cervical region. As a result of the atrophy and paresis of all the muscles of left hand, it approached the position of the "main en griffe," but the flexion of the fingers was not yet very pronounced, all the hand muscles showed active fibrillary twitching. All the extensors of fore and upper arm were distinctly paretic, but not atrophied, fibrillary contractions being present, though in lesser degree than in hand. Several of the muscles of the shoulder were also altered, for instance, the deltoid; dynamometer, 37 R., 27 L. The muscles of the right hand were also softer and thinner than normal, and presented fibrillary twitching, but so far the functions were not seriously disturbed. The extensors of the right forearm were weakened and wasting, measurement showing that the circumference of the right forearm was 1 ctm. less than that of the left. In accordance with the trophic and muscular changes, the electrical reaction was diminished. R. D. slightly present only in the muscles of the left hand and the right hypothenar, with faradic reaction diminished, but not entirely lost. There was no rigidity nor tension of the muscles. The triceps reflex was gone on both sides, the wrist reflex was lost on the left, and exaggerated on the right, side.

The lower extremities were normal in regard to trophic, paretic, and spastic alterations. Abdominal reflex equal on both sides. On the right side there was exaggerated reflex of the ligamentum patellæ, tendo Achillis, and tibialis posticus. On the left side there was ankle clonus with greatly exaggerated patellar reflex. In examining the cutaneous sensibility, no alteration of the tactile sense was found, nor of the faculty of localization or of recognizing objects by touch with the eyes closed. The whole left occipital region, left side of the neck from the lower maxilla downward, the nape of the neck, the left arm, and the whole left side of trunk were hypalgesic, analgesic, and thermanæsthetic. In front this disturbance of sensibility extended down to the inguinal fold, and behind almost to the knee. The thermanæsthesia and analgesia were almost complete in the left arm and shoulder, where piercing of the skin was painless and differentiation of boiling- and ice-water was impossible. Hypalgesia and diminished thermanæsthesia were also noted on the right hand. Secretory and vaso-motor symptoms were not present, and the muscular sense and co-ordination were normal.

Now, after having gone over the symptoms of these two cases, let me invite you to follow me on the pathological field of syringomyelia. Cavities have been found in the spine as early as in the seventeenth and eighteenth centuries, and Ollier was the first in the second decade of our century to name this condition syringomyelia. But so little was known about the connection between post-mortem discoveries and the symptoms during life, that even Erb, in his great work on spinal diseases in Ziemssen's "Cyclopædia," in 1875, classifies syringomyelia under the "rara et curiosa," and as late as 1886, Charles K. Mills and J. N. Lloyd, in their articles on tumors of the spine, confine themselves to the following statement, speaking about tumors of the spine in general: "Among the changes which occur, probably at a late stage, are the formation of cysts, either large or small, either in the substance of the cord or consisting simply of a dilatation of the central canal of the cord. This condition is known as syringomyelia, and is of exclusively pathological interest."[1]

[1] Vol. v., p. 1091, Pepper's Handbook of Medicine.

The chief alteration in this disease consists in the formation of cavities in the central gray substance, near the central canal and often united with it, seeming then to be simply a very wide central canal. We have a large central cavity in hydromyelia, a congenital malformation, and a remnant from the embryonic period. The two conditions are distinguished by the microscope when in hydromyelia we find the walls of the cavity lined with epithelium. There are cases reported in which cavities were detected post mortem, and which did not show symptoms during life. I believe that such cases belong to the congenital form of hydromyelia, and not to syringomyelia, strictly speaking. It is now generally accepted that the cavities are due to the softening, liquefaction, and final reabsorption of a neoplasma, a glioma. The gliomatous tissue forms in the gray matter near the central canal, slowly invading by its growth the spinal cord in every direction. The gliomatous tissue is very apt to undergo retrograde metamorphoses, as colloid, myxoid, or fatty degeneration. Owing to the great vascularity of the neoplasm, ruptures of blood-vessels and hemorrhage into its substance and into the adjacent parts are very common, increasing the dislocation, compression, and destruction of the cord-tissues, and forming foci of myelitic and sclerotic processes. When the white substance of the cord, with its different tracts, is invaded and compressed, then ascending and descending degeneration will take place. You understand now easily, gentlemen, how syringomyelia in its different stages and localizations may give us the symptoms of all the systemic and asystemic lesions of the cord. But syringomyelia does not limit its lesions to the cord alone. The gliomatous process invades, in the course of time, the medulla oblongata, pons, and other parts of the brain.

In turning now to the symptomatology, we find a great number of cerebro-spinal disturbances before us, in the motor, sensory, trophic, and vaso-motor spheres. The gliomatosis of the cord may extend over a long distance, even invade the whole length of the spinal medulla, but it shows in most cases a predilection for the cervical enlargement, so we see the first symptoms generally manifested in the hands, arms, and upper part of the trunk. At first sight you see the points of resemblance which this disease has with progressive muscular atrophy, a disease caused by the slow and gradual destruction of the multipolar cells of the anterior horn, leading to degeneration of the motor nerve fibres, and to paralysis and wasting of the muscles. The muscles become thin, flabby, weak, soon tire out, and, according to the number of fibres remaining intact, show every degree from slight paresis to total paralysis. In connection with the muscular and spinal changes, we see the electrical reactions altered. The faradic excitability may be normal in some muscles, in others diminished and lost; also with the galvanic current we may have normal, diminished, or no reaction or R. D. The deep reflexes may stay normal for a long time, but will be lost with the progress of muscular waste and the destruction of cord-tissue. We may find them exaggerated as the expression of secondary descending degeneration or compression of the motor tracts, and in the lower extremities we may, under this condition, often meet with adductor spasm and ankle clonus. Coming across a case presenting progressive muscular atrophy, increased reflexes, and perhaps bulbar symptoms as the expression of a pathological condition of the pons and medulla oblongata, we have all the symptoms of amyotrophic lateral sclerosis. But neither in progressive muscular atrophy, nor in amyotrophic lateral sclerosis, have we to deal with sensory and vaso-motor disturbances and trophic symptoms of a kind that will be described later on. In syringomyelia the conditions of cutaneous and deep sensibility are of paramount importance, and of a peculiar character. The subjective complaints consist often in burning sensations, or in a feeling of cold, sometimes so intense as to deprive the patients of their sleep; drawing pains or a feeling of soreness and tension, or

perhaps numbness, may be frequent. These pains and sensations are not, as a rule, confined to the course of a single nerve, but attack, irrespective of nerve-supply, regions of small size up to a whole limb. The lightning pains of locomotor ataxia are seldom met with. Very often pressure pain, or spontaneous pain of the cervical or dorsal spinal column, presents itself. But of greater value in the way of diagnosis are the objective sensory symptoms, and here we find the sense for temperature and pain diminished, even to perfect thermanæsthesia and analgesia, while the muscular and tactile senses are well preserved, including the faculty of localization and stereognostic capacity. But it is considered by some authorities that the tactile and muscular sense may also suffer in well-advanced cases.

To explain the destruction of some, and the preservation of other, sensory functions, I beg to call your attention to the following points: From the fact that the sensitiveness to temperature and that to pain are generally lost together, we may safely infer that both sensations travel in close vicinity or in the same tract in the spine, and pathological facts locate this tract in the central gray substance, near the junction of the anterior and posterior horns. A lesion affecting, like glioma, the central part of the gray matter, as a locus prædilectionis, certainly destroys first the sensitiveness to pain and temperature before attacking the tracts conducting the impressions of touch and muscular sense, located more posteriorly in the columns of Burdach and Goll.

But it must be added that Spitzka had reason to place the algesic tract at the periphery of the posterior column, near Lissauer's analgesic tract, while Gowers believes them to be in his antero-lateral ascending tract; though Birdsall, in his review on spinal diseases in Sajous's *Annual* of 1890, does not even mention the opinion of these two observers.

Of greatest interest are the trophic alterations. We have mentioned already the wasting of muscles due to compression, infiltration, and destruction of the anterior horns by the growing glioma. But as the trophic centres for the skin, hair, nails, subcutaneous tissues, joints, bones, etc., are situated near the central canal, so we can expect also morbid alterations of these organs; and really among all these patients we shall find a history of skin affections, often pemphigus-like, or of œdematous, eczematous, or erythematous character, of ulceration, of panaritia, of bone disease, especially great fragility of the bones, leading to fractures which give very little pain. In some cases of syringomyelia we find that this process goes on to destruction and loss of phalanges and whole fingers, so that such patients may give us the impression as if suffering from Morvan's disease or lepra anæsthetica; but in both the latter diseases we have to deal with a disease of the peripheral nerves, a peripheral neuritis, and though the cases may look almost alike we shall, after careful examination and longer observation, be able to differentiate. One point is to be kept in mind, viz., that the preservation of tactile sense will decide in favor of syringomelia, for this sense will suffer alike with the senses for temperature and pain in lepra, peripheral neuritis, and Morvan's disease. The joints show a number of affections: Chronic and acute inflammation, arthritic processes, thickening, anchylosis, etc. It is an open question whether the kypho-scolioses so often found in syringomyelia are not due more to trophic influences on the joints and bony structures than to faulty equilibrium of the supporting muscles.

Of vaso-motor disturbances I may mention stasis, ischæmia, and hyperæmia; of secretory changes, anhydrosis, hyperhydrosis, and alterations in the secretion of saliva and tears.

In regard to differential diagnosis I may say that a confounding with locomotor ataxia can be easily avoided, as the condition of the reflexes, of the muscular sense, etc., should be sufficient to keep one from error. Chronic cervical pachymeningitis may be mistaken for syringomyelia, but the absence of symptoms arising from lesions of the central gray matter, the rigidity of the muscles of the neck, and spastic condition of other muscles and other symptoms, would rather point to meningeal affection. Certainly when gliomatosis has enroached also on the meninges, a differential diagnosis may become almost impossible.

Cases are known where the differential diagnosis between hysteria and syringomyelia was certainly not easy, and with your leave I beg to quote from Birdsall's report on spinal diseases in Sajous's *Annual* for 1890, page 26. B. Charcot, in a clinical lecture reported by Blocque, calls attention to the possibility of mistaking hysteria for syringomyelia. The character and sensory disturbance of the latter, namely, loss of sensibility to pain and thermal changes, with preservation of tactile sensibility, is a form found in hysteria, and may also be induced by suggestion. He relates a case, however, in which "this great simulator of organic diseases" imitated syringomyelia in a still more remarkable manner than by sensory features alone.

He exhibited a patient presenting loss of motility in the thumb and fingers of one hand, an œdematous tumefaction of the dorsum of the hand, loss of the pain and temperature sense of the head, with the lower fifth of the forearm, with normal tactile sensibility. The history of the case shows that on a previous occasion he had had a similar attack (except that then the tactile sensibility was also impaired) which ended so abruptly that he remarked, "If I had been at Lourdes, I would have considered it a miracle." The duration of the first attack was about a year. After an interval of months the trouble returned suddenly. Evidently a case of hysteria in the male, and not syringomyelia. In regard to the etiology of syringomyelia, not much can be said. Heredity, alcohol, injuries, etc., do not seem to have much influence in its causation. As to the course of syringomyelia, I may state that there is no certain rule in the appearance and succession of symptoms; vaso-motor, trophic, sensory, and motor symptoms may precede or follow each other or appear combined. The disease extends over a number of years, from ten to twenty, not without seeming improvements and intermissions which often last quite a period. It must not be forgotten, however, that from the nature of the disease sudden exacerbations, the result of hemorrhages, etc., may be expected.

The therapeusis is confined to symptomatic and palliative treatment. The physician can certainly do much to relieve the suffering of his patients, but care is to be taken not to establish the morphine habit in the effort to relieve the often excessively painful sensations. The iodides, counter irritation to the spine, electricity, care for proper hygienic surroundings, tonics, etc., all will help to prolong life and make it more comfortable.

Removal of the Gasserian Ganglion for tic-douloureux has been done for the fourth time in London by Mr. William Rose. We understand that it has been done once in this city.

French Hospital in Constantinople.—The Sultan has issued an order authorizing the construction of new buildings for the French hospital in Constantinople. These will be quite extensive, covering an area of nearly two acres.

WHAT CASES SHOULD BE DRAINED AFTER ABDOMINAL SECTION.[1]

By RUFUS B. HALL, M.D.,

SURGEON TO THE CINCINNATI FREE HOSPITAL FOR WOMEN; CLINICAL LECTURER ON GYNECOLOGY AT THE MIAMI MEDICAL COLLEGE, ETC., CINCINNATI, O.

At the present time there seems to be a considerable difference in opinion and practice in reference to drainage after abdominal operations. Some operators, relying upon strict antiseptic methods in their work, discard drainage almost entirely; there are others who are just as painstaking in every detail pertaining to antisepsis and cleanliness who use the drainage-tube very generally, and a few who drain after every section. Between these extremes there are many grades of opinion and practice. There are many reasons why drainage should be generally employed after abdominal operations. To a few of these I shall briefly direct your attention. We may have observed every antiseptic precaution in any given operation, yet who can say with absolute certainty that nothing had been overlooked, or that some break in the technique had not occurred which would cause septic changes in the fluid retained in the abdominal cavity after an operation. We may leave the abdominal cavity as clean and dry as possible at the time of closing it, yet there is always more or less accumulation of fluids during the first few hours following every operation. The fact that the retained fluid may become septic, and thus a source of danger, was observed and commented upon by Sir Spencer Wells, in 1859. The fourth case operated upon by him died in thirty-two hours afterward. At the autopsy he asked "Did she die of peritonitis?" There was serum in the peritoneal cavity, but he very significantly expressed a doubt if simple peritonitis was sufficient to cause such sudden collapse and death. He declares that if peritonitis killed her, it was indirectly by the formation of a morbid process. In seventeen autopsies recorded in Wells's first volume, published in 1865, he reports the presence of serum within the peritoneal cavity in every case, and none of those cases were drained. He describes it as "turbid serum," "red serum," "blood-stained serum," in varying quantities, from a few ounces to one pint or more; in every case death followed in from twenty-four to seventy-two hours. In examining the report of the autopsies in Baker Brown's series of one hundred and eleven cases you will find recorded that "within the pelvis was found a little bloody serum." When we recall the fact that the peritoneum is a large lymph-sac, and that the fluid within is taken up into the circulation with great rapidity, we can understand why these cases are overcome so rapidly by the absorption of a concentrated septic fluid; which condition we might have in any given case where drainage was not employed. It has been the prevailing opinion until quite recently that peritonitis was the cause of death in a large per cent. of those cases dying after abdominal operations, and the leading writers of but a few years ago state that peritonitis was the cause of death after ovariotomy in from twenty five to forty-three per cent. of all those dying after that operation.

In reviewing those reports with our present knowledge of the after-management of these cases, I am convinced that those writers recorded cases as dying from peritonitis, which we would not record as deaths from sepsis, or perhaps septic peritonitis. We have devoted too much attention to the treatment of peritonitis after operations, and thus overlooked the great source of danger, that of the accumulation and retention of serum in the abdominal cavity, and its rapid decomposition and subsequent poisoning from its absorption. The late Marion Sims fully appreciated the dangers arising from this cause and gave expression to his views in the following words: "There is no more reason why the system should not be overwhelmed by the absorption of concentrated septic fluid than by the rapid absorption of an over-dose of morphia." With these facts before us voicing the opinions of the eminent surgeons named regarding the dangers of fluid remaining in the peritoneal cavity after operations, we are amazed when we consider the long time it has taken to establish upon a firm basis the advantages to be derived from abdominal drainage. Again, when we consider the number of operators at the present time who only use drainage in complicated cases, in which there has been extensive adhesions, we are forced to believe that they have not given their patients the best chance for recovery. The amount of bloody serum removed from the peritoneal cavity after many of the simplest of the pelvic and abdominal operations is incredible to any one not accustomed to draining after such simple operations. This fluid may be perfectly harmless, I have but little doubt, so long as no decomposition takes place, but if that occurs the patient is in great danger. It is certain that if we remove all fluids as fast as formed there will be no danger from such a source. To leave the cavity undrained for the peritoneum to dispose of the fluid is to tax unnecessarily the powers of nature, a burden we as operators have no right to impose upon any patient when we have such a simple and harmless procedure at our command. The fact that nature is competent to dispose of the fluid accumulation in the majority of the mild cases is no argument to use against the employment of universal drainage; especially is this apparent when we recall the fact, which every one must admit as true, that no man can tell to a certainty in any given case whether or not nature can or cannot accomplish that task.

So far as I am aware, I am the first one to employ universal drainage after abdominal section. I have drained in every case of abdominal section which I have made since September 23, 1886, with but one exception, and I do not feel called upon to apologize for my results, except in one case, and that case was not drained and the patient died. This death I am now reasonably certain could have been averted had the case been drained. The patient was forty years of age, suffering from a bleeding fibroid of the uterus. The tumor was the size of a cocoa-nut and dipped well down into the broad ligament. The uterine appendages were removed without difficulty as there were no adhesions. The operation was a perfectly easy and simple one, and was made at the patient's home, and I was unable to see her afterward. As the tumor almost filled the true pelvis, I could not place a glass drainage-tube so as to drain the pelvis, and I decided not to drain it at all. The patient died fifty hours after the operation, with a high temperature and rapid pulse. At the autopsy several ounces of blood-stained serum were found in the peritoneal cavity. She died from sepsis.

I occasionally encounter cases at the time of closing the abdomen in which it appears as though a drainage tube was not necessary; still we are treated to the most extraordinary surprises, and in not a few of these very cases secure large quantities of blood-stained serum. Again, if there is hemorrhage the drainage-tube will notify us of its occurrence, and if there should be any difficulty developed about the pedicle the drainage-tube leaves a track to the surface that may be followed by any fluid which may be formed at that point. If we have placed the drainage-tube in a simple case, and at the end of eight or ten hours it is found that the case is one which does not require drainage, the tube can be removed without disturbing the patient in the least, and it has done no harm. If, on the other hand, this same simple case should have been one requiring the use of the drainage-tube, you have put the patient in the best possible condition to recover by its use.

In operations for the removal of the uterine appendages in long-standing inflammatory diseases, we find the adhesions always firm and extensive, and no abdominal operation can test so thoroughly the efficacy and utility of drainage as does that operation in these chronic cases. And here, where every case was drained, I have had a series of thirty-four consecutive cases with-

[1] Read before the Ohio State Medical Society, June 17th, 1891, at Sandusky, O.

out a death. I mention this to illustrate the point I wish to emphasize in this paper, a point I believe which is not duly appreciated by many operators. If we place reliance upon drainage, and not upon the absorptive powers of the peritoneum, we will have no reason to regret it, and we will save not a few lives which would otherwise be lost. In this branch of pelvic surgery I am certain every operator will agree with me that the adhesions are both firm and extensive, and on account of the large surface denuded of peritoneum these cases require the use of the drainage-tube for a longer time than most other abdominal operations, testing thoroughly its powers for good. The cases referred to I took as they came, both the good and the bad, all were feeble from long suffering and repeated attacks of inflammation; a few were bedridden, and two were brought in on the stretcher.

The objections to the drainage-tube that have been given at various times are that it is a source of septic infection, a frequent cause of hernia, a foreign body, a cause of irritation, and not infrequently omentum becomes fastened in the perforation, preventing its easy removal. As to the first objection I have seen no case of sepsis developed from the use of the drainage-tube; but it is evident that unless the utmost care is taken such an accident might occur. The tube should be pumped out every hour or two until it is removed. In my own cases I have seen two hernias developed in the line of cicatrix, but in neither of them did the hernia occur at the point where the drainage-tube was placed. I have seen no appreciable disturbance from irritation of the tube since I commenced using the small, perfectly smooth tube with no side perforations, which I had made in September, 1888, and used until October, 1889, when I substituted the small, perforated tube of Dr. Price, which fulfils the requirements for abdominal drainage perfectly. If the dressing is so arranged as not to make pressure upon the outer end of the tube, no apprehension need be entertained as to it causing trouble from irritation, provided it be removed just as soon as the fluid becomes straw-colored. If one employs the old-style large tube, with large side perforations, there is danger of omentum becoming forced through the openings, causing difficulty in removing the tube and possibly favoring the development of hernia; but in the use of the small tube with the narrow perforations spoken of, these dangers are reduced to a minimum.

With these facts before us, I am convinced of the wisdom of universal drainage after abdominal section. I am aware that this will be considered by many as a useless and dangerous procedure, nevertheless I believe that it is correct. I have saved the lives of several patients by putting in a drainage-tube when it was apparently not indicated. So long as I can say this of a single case, and so long as drainage is the harmless procedure that it now is, I shall continue to give my patients the benefit of the doubt by draining every case in which the peritoneal cavity has been opened.

154 West Eighth Street.

The Treatment of Dysentery.—At a meeting of the Medical Society of London, held October 19, 1891 (*Medical Press*), Professor Bahadurji, of Bombay, read a paper on the treatment of dysentery, which he said was not a contagious or infectious disease, nor in any sense specific. He claimed to have reduced the mortality to almost nothing. Instead of endeavoring to keep up the strength of the patients by meat juices and extracts, which he said acted only as irritants, he gave arrow-root milk. In the way of medication he gave bismuth, Dover's powder, and soda, with the object of neutralizing the acidity of the blood, of calming the abnormal action of the glands of the large intestines, and of rendering the canal sweet and free from decomposition. He pointed out that the action of the ipecac and the alkali was to render the thick, sticky mucus more liquid, and thus enable it to be got rid of.

THE UPPER AIR-PASSAGES AND THEIR DISEASES.[1]

By O. B. DOUGLAS, M.D.,

Surgeon to Manhattan Eye and Ear Hospital, Throat Department, New York; Professor of Diseases of the Nose and Throat in the Post-Graduate Medical School and Hospital; President of the Medical Society of the County of New York; Fellow of the Academy of Medicine, etc.

If we attempt to analyze human life we discover its complexity and vastness. The science that would comprehend it in its origin, continuance, and end is of necessity broad and deep. It must name and record all physical parts, must observe their functions and relations to other parts, note their normal and abnormal conditions, know the means for preventing impairment and for restoring health. It must explain the relations of mind, memory, and reason to the physical, must survey the invisible borderlines of sanity, sleep, and death, and mark with exactness their limits.

As exponents of this science—that comprehends every other science—we are expected to disentangle with certainty and celerity many of its mysteries; to discover the causes and cures of all maladies, and be always ready to apply the proper remedy; to stand ever on guard ready to protect the health of individuals and of communities. At times we are made to realize that no intelligence below that which created human life can understand it, and we are overwhelmed by a realization of the responsibility we have assumed. But the world—and the science of medicine—progress, and we are in the grand struggle to advance. No man ever did better than we may do.

Practically, how can we best succeed? How can we know and do that which others are doing at their best? We shall never attain much beyond our aspirations. With the purpose comes the strength. We have to learn from those who give their concentrated attention to special branches, and gather the results of their experience.

All physicians cannot be specialists, the opportunity does not come to them to study a large number of similar cases. But in densely peopled sections—our large cities—it is difficult to prevent specialism. A successful treatment of what the patient considers a serious case, is sure to be spoken of among his friends, resulting in a new crop of patients with similar troubles. And, struggle as one may against it, he wakens to the fact that he is a specialist, treating largely a certain class of cases, the tendency being ever to narrow the field of operations and the operator. Good men struggle against this tendency, and learning something from each specialist—and much from them all—grow broad and mighty in mind and practice. They show their wisdom not in studying special departments less, but in studying all departments more.

I have the honor to speak to you upon a subject to which I have been compelled—by force of circumstances and my own volition—to give much attention. The upper air-passages and their diseases I believe to be well worth your careful consideration, and justly demand more study than has been given to them. If I urge this with earnestness it is to impress its importance—as the sharp stroke of a hammer is more effective than its simple weight. And when I declare diseased conditions of the nose and throat cause more suffering—directly and remotely—than those of any other organ in the human body, I express what I firmly believe to be true, and indicate the relative importance of a knowledge of these parts and their diseases.

Catarrh, so-called, is more universally prevalent than any other disease which afflicts the human family. It is more persistent in its course from bad to worse, involves more vital parts, affects remotely more important organs, and is more destructive to the achievements of life than any other disease—absorbing vital force when it does not destroy, and blighting where it may not consume. That, in a large proportion of cases, it can be

[1] Read before the Vermont State Medical Society, at Burlington, October 15, 1891.

cured, is no longer a problem to be solved. Catarrh is an effect of causes that may be removed. Charlatans, discovering our inactivity, have rushed in to possess this veritable Eldorado, realizing larger returns for their enterprise in this direction than for any and all other ventures.

In the medical, as in the commercial, world, success crowns the man who is ready to supply a large demand. Quick sales and small profits bring, in the aggregate, larger wealth than slow sales and large profits. If we can quickly relieve woes common to the masses we may win success; and this not in a pecuniary sense alone, for the true lover of his fellow-men seeks to do the greatest good to the greatest number with least delay.

If we are justly impressed with the importance of this branch of medical science, we shall find its study neither dull nor uninteresting. The anatomy, physiology, and histology of the nose and accessory sinuses, the mouth, fauces, pharynx, larynx, and lungs, the eyes, ears, and brain, will afford an ample field for investigation, while the pathology, therapeutics, and surgery give large opportunity for practical work. Material is always abundant; our hands need never be idle. The recompense is reasonably sure, that better part—the consciousness of giving great relief to suffering—which constitutes the major portion of every physician's compensation, is adequate.

Success in treating diseases of the upper air-passages—like success in other work—is the product of skill; but skill is largely acquired, and comes from experience; hence the need of application, of improving every opportunity for making a personal examination of noses and throats.

We should know the dangers to which these organs are exposed, their diseases, and necessities. We should learn to detect their assailants, to diagnosticate their pathological conditions, to differentiate the simple and complex, the benign and malignant; to decide what conditions should be soothed, what stimulated, what constringed; when medicines will cure and when surgery is required; what drugs are best, what operations needed—whether ablation, abscission, evulsion, or cauterization—and by what method. We should possess the best instruments and learn how to use them. Thus we will add dexterity to knowledge, and to science art.

We are living in an age of investigation, the etiological period of the world. Men challenge theories. Antiquated methods are criticised; that which bears the sacred seal of classic age is not exempt from prying eyes and polished shafts of sceptics. Ignorance is no longer a subterfuge of safety.

It is not necessary that we should consider at this time the anatomy of the upper air-tract, further than to observe its intimate connection with other organs. By continuity of tissue the nose is related to the maxillary, ethmoidal, sphenoidal, and frontal sinus; through the cribriform plate of the ethmoid to the brain and meninges; by way of the lachrymal canals to the eyes; by the Eustachian tubes to the ears; by the pharynx to the base of the tongue, the larynx, trachea, and lungs; by the œsophagus to the stomach; by the fauces to the mouth. The character of these various tissues, the mucous membrane, the vascular system, and the nerve-supply of the nose are interesting and profitable, and should be carefully studied. A want of time prevents our reviewing them here. The physiology and functions, the uses and abuses of the nose might well take more than all our time to-day. We may glance at the pathology, the therapeutics, and surgery, and consider briefly the causes, course, and cure of diseases of the upper air-passages.

What diseases most frequently attack these important organs? They are exanthematous, diphtheritic, tubercular, syphilitic, carcinomatous, scrofulous, erysipelatous, and inflammations resulting from irritants inhaled or ingested, traumatism, hypertrophies, and foreign bodies.

Catarrh is a secondary effect of these various causes, and is associated with hyperæmia, hyperæsthesia, and hypersecretion. Sneezing, coughing, obstructed respiration, pain at the bridge of the nose, superior maxillary and supra-orbital regions, through the eyes, ears, temples, and back of the head, are some of its symptoms or results.

Traumatic causes of catarrh are much more numerous than all other causes combined. I do not mean the immediate result of injury, but its more remote effects, discoverable after a lapse of years as deflected septa, exostoses, and ecchondromata.

The immediate effect of the diseases named are local and general. Their effect upon the general system must be carefully watched and combated. The patient must be treated, not simply his disease. We cannot enumerate here the effects which these diseases exert upon the general economy, nor discuss the question whether they are the primary lesions, or the local expression of general lesions. We know the attack is made somewhere, upon some part first, and I see no reason for doubting that the germs of scarlet fever, diphtheria, tuberculosis, and many other diseases may be received into and locate upon the most exposed of all parts of the body, notwithstanding nature's extraordinary effort to fortify the nose and throat against such attacks.

The local effects are manifested by an increased flow, often muco-purulent, from the nose, anteriorly and into the throat, by pharyngitis, uvulitis, tonsillitis, laryngitis, bronchitis, and gastritis; by mouth-breathing, asthma, hay-fever, and hoarseness; by ringing and other noises in the head, by partial or complete deafness, inflamed eyes, nasal voice, anosmia, and impaired functions generally.

Of the universality of these diseases and their dire effects, we note: they prevail from Maine to California, throughout all climates, at all seasons, among all people, through all classes, at all ages, in every generation.

The persistency of chronic catarrh is proverbial. Like lepra, it is reputed incurable. It has baffled the sages, mocked at assailants, defied the schools, laughed at "pathies," and held its sway. "Faith-cures" have failed as signally as execrations of the damned.

Like all persistent ills, it has had "remedies" innumerable. Snuffs, sprays, gargles, ointments, washes, swabbings, probings, powders, inhalants, blood-purifiers, respirators, inspirators, and finally expirators. Failures have been almost as numerous as attempts to cure catarrh. In my experience at the Throat Department of Manhattan Eye and Ear Hospital, since 1877, many pet plans and proposed methods for curing this condition have been distorted by practical tests and common sense, till their gnarled features are hardly recognizable. Yet, positive and wonderful progress has been made, and there is a survival of very excellent methods. The interest felt by our profession in this branch of the science has increased greatly in the last dozen years. From an ignored and almost unknown work of a few years ago, it is now justly attracting thoughtful men. I was impressed with this fact a few months ago, when, wishing to know what had been written for the Medical Society of the State of New York, I examined its published Transactions from the organization in 1807 to the present year, and was surprised to find no reference to these diseases during the first seventy-three years of its existence. The first evidence we have in its publications, that this Society considered catarrhal diseases worthy of its consideration was from the pen of Dr. D. B. St. John Roosa, in 1880, "On the Evil Consequences of Neglected Colds in the Head." During five years from 1880, nine papers were published calling attention to diseases of the upper air-passages. In the succeeding five years, sixteen papers on this subject found places in their Transactions; while in the last two years, thirteen papers on these diseases were presented to that Society. This shows an awakened interest in this department of medicine hardly equalled in any other. But I cannot think we have yet reached a just appreciation of its importance, or are likely soon to overestimate its value.

I have stated that traumatism is the cause of more catarrhal trouble than all other causes combined. It so far outnumbers other causes, and produces effects that best typify what we see and understand as catarrh, that this, alone, may profitably occupy all the time we have for this subject to-day. Bosworth states, in his recent work on "Diseases of the Nose and Throat," that, "Deformities of the nasal septum are probably the most frequent of all exciting causes of catarrhal inflammation." Certainly, the most frequent causes of these deformities are traumatic. Everybody has experienced the instability of uprightness, the uncertainty of our steps, the proneness to stumble—in childhood, if not since. The contusions from falls in early life, from fisticuffs a little later, from balls and bats and various accidents that befall this protruding feature, are quite sufficient to displace the septal cartilage and bring it in contact with some portion of the outer wall of the nose. By careful count and computation, four-fifths of all septa in dried skulls are distorted. We may add a large percentage of the remaining fifth, if we count deflections of the cartilaginous septum during life. Every deflected septum does not cause catarrh, something beside simply a deflection is necessary. But every persistent contact of surfaces that are not normally in contact in the nose will produce the condition we are calling catarrh; and further, this condition never exists where there is not, or has not been, some abnormal contact or obstruction. It is not necessary that there should be an occlusion of the nostril, an adhesion of surfaces, or even obstruction to respiration. Our attention has often been called by writers upon this subject, to the necessity of free drainage and an open respiratory tract. This is certainly not unimportant. But other obstructions may exist, obscure but of immense moment as etiological factors. Little points of contact are found to be the cause of great trouble. We observe a good percentage of patients who have a dropping into the throat, with chronic pharyngitis and offensive breath, yet can breathe freely through both nostrils.

To this condition, then, of abnormal contact of surfaces of septum and turbinated bodies—more frequently the middle—I want to urge your special attention in every case of catarrh. It may result from a deviation of the septum, or from congestion or hypertrophy of the turbinated tissues, from an osseous or cartilaginous spur, a cavernous turbinated bone, a polypus, foreign body, or other obstruction.

I read in some of our books that a "catarrh is the prime and great cause of hypertrophies and the narrowing of the nasal passages." If this be at all true, the reverse is certainly true. Contact causes catarrh. There is no doubt that the physiological function of erectile tissue in the nose, recurring at frequent intervals, does destroy the elasticity of the parts, and hypertrophic, or, more likely, hyperplastic changes result This produces the condition we speak of as hypertrophy. bringing surfaces in contact.

Here another stage in the causation of catarrh begins. The secretions so abundantly poured into the nasal fossæ, which are normally alkaline and bland, being retained in this most favorable situation for rapid deterioration, speedily become acrid and irritating to the tissues over which they pass, as they overflow their prison bounds. These tissues in turn become inflamed and carry forward the devastation. It is thus that catarrh becomes chronic, tending ever to grow worse and extend its ravages to all communicating and accessory parts, its putrescent vapors to the lungs, and putrid matter to the stomach.

Otologists tell us that nine-tenths of all deafness results from middle ear disease, induced by nasal and pharyngeal inflammation. Dr. Roosa, in the paper referred to, speaks of "hypertrophied tonsils, thick voice, impaired hearing, narrow chest, and watery eyes," as results of neglected colds in the head. And I believe that bronchitis, laryngitis, tonsillitis, faucitis, pharyngitis, hypertrophic rhinitis and gastritis, being associated with are often caused by nasal catarrh.

We must not forget or fail to recognize numerous characteristic neurotic troubles caused by this contact of surfaces in the nose. The so-called catarrhal headache, supra orbital neuralgia, pain at the bridge of the nose, at the back of the eyes, in the ears, through the various sinuses—superior maxillary, ethmoidal, sphenoidal, and frontal—in the teeth and throat, and wherever branches of the fifth nerve may be distributed. Hay-fever and asthma are often, if not always, sequelæ of nasal irritation and belong in that large list of reflex or remote manifestations of local causes in the nose. Dr. Jacobi stated in a recent discussion of reflex causes of disease, at the New York Academy of Medicine, that "he had seen at least a dozen cases of chorea which had no other cause than chronic naso-pharyngeal catarrh, deviation of the septum, ozæna, hypertrophy of the tonsils, etc.;" and Dr. Baruch on the same occasion said: "The first positive case which removed my scepticism on the reflex influence of nasal peripheral irritation, is a cure of true epilepsy," and he related the history of this case and its cure by removing the cause in the nose.

If evidence were needed of the baneful effects of catarrh and all it implies, volumes might be written and opinions of recognized authority be multiplied to almost any extent.

The important question remains, How can catarrh be cured? "Is the cure of chronic nasal catarrh as difficult as has been supposed?" I tried to answer this question in a paper read before the County Medical Society of New York two years ago, and published in the *New York Medical Journal*, March 22, 1890. The conclusion arrived at was, "It is not so difficult to cure as by many has been supposed, for it is the result of removable causes in most cases." Having discovered the foe and its lurking place, it does not require a Hercules to destroy this Hydra, or if it does, our present age can provide the man. Common sense and skilful surgery are as potent as the club of the deliverer of Argos.

Remove the cause, which almost always may be found. The most frequent—because of its limited space and greater exposure to irritants and injury—is the middle turbinated body. Its pressure upon the septum is, I venture to affirm, the forerunner of a longer train of evils than any other simple pathological condition to which human flesh is exposed. Take away, by any means or instruments which you can use best, just a sufficient amount of tissue to relieve contact, and you will almost certainly cure your patient of catarrh. I must urge you to consider most carefully the various complications that may arise, the time and after-treatment required, the necessity for suppressing granulation-tissue that is prone to grow, the danger from operations so near a vital part, the conservatism and wisdom to be exercised in all these cases But I cannot here consider drugs found to be useful, the means for disinfecting and keeping the parts cleansed, the constitutional treatment needed, the instruments, appliances, etc.

The importance of frequent applications to a diseased condition of the nose or throat can hardly be overstated, whether the disease be diphtheria, tonsillitis, a common cold, or any of the numerous conditions for which we use medicines. Whatever local effect is produced by medicine applied to these parts is quickly dissipated by the secretions which are so abundant, by constant use of the organs, and the impossibility of retaining for a considerable time anything in the throat. Decomposition of organic substance and absorption of the products, ptomaines, etc., produce septicæmia, and to prevent this result we must remove the cause. Cleanliness is indicated and essential, as in all surgery. To destroy the rapidly multiplying germs of diphtheria, and other diseases akin to it, we should order medicines to be given every fifteen minutes, day and night, from the first indication of the disease till its last appearance in the

throat. These remedies need not and should not, be disagreeable to the patient, but their invariable frequent administration should be enforced.

I cannot take your time to relate cases cured by the treatment I have indicated for diseases of the upper air-passages. They are sufficiently numerous to have convinced me of their utility. More than seventy-five thousand visits have been made by patients at the Throat Department of Manhattan Eye and Ear Hospital since my service commenced there, and with fourteen trained assistants we have studied and tested these methods thoroughly.

Ever since "The Lord God breathed into his nostrils the breath of life, and man became a living soul," every child born has received the same benediction, in the same manner. And so long as life lasts should the functions of the nose and throat be preserved in their integrity.

123 East Thirty-sixth Street.

THE EXTRACTION OF INCIPIENT CATARACT.

By S. DICKSON BARR, M D.,

PHILADELPHIA, PA.

My object in writing this article is to impress upon the profession the feasibility of the extraction of cataract in its incipiency and its advantages over the practice of waiting until the cataract is mature before operating.

I do not wish to force these ideas or opinions upon the fraternity, but to put them in such a light that there may be seen in them some food for thought, perhaps sufficient reason to justify them in testing the truth of the theory.

We all know the frequency of cataract and its complications, that too much study and thought cannot be given this particular subject. But, as far as I know, nothing has been written relative to the best time for operating before my paper in the New York *Medical Journal* of last September.

Since that time I have received a number of letters in reference to it from men in different sections of the country. Seeing the interest it had caused, I believed that an article discussing the subject more fully would not be amiss.

Every oculist has a fair percentage of cases of cataract in all stages of growth. In all cases the verdict has been, wait until the cataract is mature, with the exception of those of traumatic origin of dangerous character, and also those that are already ripe.

There has been no question as to the time for operating, except in critical cases. It was an understood law that the patient must wait until the cataract was mature or ripe, which meant the inability to distinguish anything but a light in a dark room.

This necessitated waiting for months and sometimes years, and caused a great deal of trouble, dissatisfaction, and inconvenience, not only to the patients themselves, but to their friends as well. Sometimes the cataract remains in a quiescent state, neither growing any worse nor any better, causing the patient to be in a semi-darkness for years in the hope that it may mature and become hard enough to remove.

This term of waiting is a question of great moment, and we must consider the advice as given above in all its phases: what it means to the patients, what it means to their friends, and, through these two factors, what it means to us.

The question is, Can we, by any means with justice to the patient and ourselves, prevent this long term of waiting and consequent distress?

We can by performing an operation in the early stage of growth; at the same time we get a better result, with a much smaller per cent. of after-trouble, than by waiting.

If this is so, then we save our patient and his friends a great deal of trouble, give a good vision, and cover ourselves with glory in their eyes.

Should we send the patient away with the advice to wait, we would be very apt to lose him, since he would likely consult some other specialist, and should this one prove to be bolder than we, the case is sure to be lost to us. We lose the case through a fear of operating too soon, which fear I now know to be unjustifiable.

To begin at the beginning, we must first take a cursory glance at the anatomy of the parts.

The crystalline lens is a bi-convex body placed directly behind the iris, the anterior surface touching it for a considerable area. It is situated in the hyaline fossa, a depression in the vitreous, and is held there in a capsule by the suspensory ligament, or zonula of Zinn.

The lens is composed of long fibres or cells arranged in a concentric manner. These fibres are laid down at the periphery, and the lens being in a capsule the central fibres are compressed and packed closely together. This growth continues to the end of life, the lens becoming more and more compact. The gradual loss of accommodation confirms this fact.

Donders represents that the refractive power of the eye is at its maximum in a child of ten years of age, and that from that time it gradually decreases, until at the age of sixty years it is lost altogether.

What is the cause of this and what does it signify?

Certainly the ciliary muscle does not begin to degenerate at this early age.

If it is not the ciliary muscle, then it must be the crystalline lens which changes, since these two are the only factors concerned in the accommodation.

We now understand that the lens after the age of ten years grows more and more solid and compact every year, and after the age of sixty years is in such a condition of solidity that it cannot be changed by any amount of action or effort on the part of the ciliary muscle. But we know that the accommodation for near vision is lost about the age of forty years, showing that the lens is quite solid by that time.

A cataract is a change undergone by the crystalline of the nature of degeneration and not from any inflammatory conditions. It is a shrinking of the fibres, an atrophic change. As this change goes on the lens substance grows brittle and scaly, the fibres are dead and without sufficient adhesive power to hold together, they change into molecular detritis.

Those here who have operated upon an old or mature cataract are aware of the fact that small particles of lens substance are almost invariably left in the eye and have to be removed after the lens itself is extracted, and all the particles cannot then be always taken out, but remain to form a secondary cataract. It may always have been noted how easily the fibres of the lens can be separated and small pieces scaled off after extraction. It is not so with the cataract in the stage of incipiency. That is a mass of the consistency of gum, smooth and solid. The lens is not opaque, but clear, with the exception of a few cloudy streaks, the depth of the opacity being dependent on the length of time the degenerative changes have been going on.

Those who have been in eye dispensaries and hospitals have, no doubt, seen cases in which, from traumatism, there was dislocation of the lens and perhaps imperative necessity for removal. The operation has been successful, resulting in good vision, in those cases where there were no complications. Among them have been lenses which were not opaque in the least, and were removed because they were in a position where, if they remained, they would likely cause a great deal of trouble.

Why should these operations be successful and not the one for incipient cataract? One case in particular that I know of: A man, some years ago, came to Moorfields, the London Eye Hospital, having been kicked in the face by a horse. On examination it was found that the corks of the shoe having struck the inferior portion of both eyeballs, had driven the lenses out of their position and lodged them in Tenon's capsule, from which position they were removed by merely opening the conjunctiva. The man had good vision after.

The capsule is not ruptured? I will allow that and still the fact remains. I am arguing for the kind of operation to perform. Remove the incipient cataract, in the capsule, if you will, but remove it. At the same time it makes no difference whether the capsule is ruptured or not after the age of forty-five, with some few exceptions.

I know this from experience, as I have invariably opened the capsule without any ill results. These cataracts, when removed in their incipiency, are hard and smooth, and so clear that I have taken them between my fingers and read small print through them enlarged to two or three times the original size by the magnifying power of the lens. They have really not become cataracts.

In cataract operations I have had less trouble, less loss of vitreous, and better vision obtained, as a rule, the earlier the operation.

In operating for cataract I usually follow von Graefe up to the capsulotomy. In rupturing the capsule I use a right and left cystitome with a sharp, knife-like point. It is passed through the wound in the superior portion to the lowest point on one side of the lens and inside the dilated pupillary margin of the iris. The point enters the capsule at this low point only of sufficient depth to cut it and escape tearing the cortical of the lens. It is best to have an assistant to focus a strong light on the lens. It is then drawn up, delicately making a clean cut through the capsule. The same operation is done on the opposite side, then horizontally in the inferior portion, connecting the two vertical cuts as low down as possible. The next cut is in the superior portion, just at the edge of the lens. By doing this we cut out a large square piece, almost, if not quite, as large as the lens itself, and this can be removed along with the lens. In this manner of cutting the capsule we have an additional clamp on the cortical, since the lens has not shrunk sufficiently to separate the two. Now, instead of pressing on the inferior portion of the cornea with a spatula to force the lens out of the cut, I sometimes use a Crichett's spoon, passing this through the wound in front of the lens, catching it in the inferior part. At the same time a curved spatula is passed posterior to the lens in its superior portion in order to tip it forward into the wound. Then by carefully lifting the scoop the lens comes out entire, also the anterior portion of capsule, without the least trouble or the use of any force. There is no capsule remaining to form secondary cataract, not even enough to roll up and hold any lens substance which might give after trouble.

By operating thus early our percentage of successful operations will increase, since the lens will be removed before it has an opportunity to form cataracts that are troublesome. We also do not run the risk of the lens growing hypermature and the consequent difficulties.

There is hardly anything more to be said, except, try for yourselves and see. Don't keep your patient waiting, as his patience, as well as yours, will vanish like a summer dream.

I give here a compilation of a number of cases with their vision before and after operating:

MANAGEMENT OF THE PAROXYSMAL INEBRIATE.

By L. B. TUCKERMAN, M.D.,

Clev. Land, O.

The assertion so confidently made by some to the effect that paroxysmal inebriety can be "radically cured," seems to me open to serious question. I have seen altogether too many "cured" cases relapse. There is little doubt, however, that under proper management the duration of the paroxysms can be materially shortened, and the intervals between them prolonged to such a degree that, in the majority of cases, the disease need no more interfere with a man's business than a gouty diathesis with occasional acute exacerbations. But to attain this result the condition must be treated as one of disease pure and simple, and the family and friends of the patient must heartily co operate with the physicians in enforcing the necessary discipline. If the patient will himself co-operate, so much the better. The plan of treatment which has proven most effective in my own hands is as follows: The patient is put to bed and kept there for three or four days under the constant care of a nurse; if the patient be allowed to go about he does not recover physical tone as soon, and if he be left alone any length of time the fits of mental depression into which he is certain to fall greatly retard his recovery. Alcoholic liquor in every form is withheld from the first. Hot broth is given every hour, and hot milk at the usual meal times. Strychnia ($\frac{1}{30}$ to $\frac{1}{120}$ grains of the sulphate) is given every hour, and in case the heart acts feebly or the kidneys are sluggish it is combined with $\frac{1}{130}$ grains of digitalin. At night a sedative is given subcutaneously. Terchloride of gold and sodium ($\frac{1}{25}$ grains in thirty minims of water) has seemed to act kindly—more so than preparations of opium, either alone or combined with atropia or hyoscyamia, or those mixtures containing chloral or bromides. Coffee, hot, and without milk or sugar, is allowed if the patient cares for it. Irregularities of the stomach and sluggish action of the chylopoietic system are corrected with small doses of calomel ($\frac{1}{10}$ grain three to six times a day), combined with ipecac and soda. After the third day the patient is allowed to sit up, and easily digested solid food, such as rare beef-steak, etc., is added to his diet. From the fifth to the eighth day the nurse can usually be dismissed, and the patient returns to his business free from the craving for liquor for the time being. I add the qualification advisedly, for over-work, or over-worry, or prolonged privation of sleep, or any other cause which lowers the reserve of nerve-force below a given point, will occasion a return of the craving, and with this craving comes the delusion of dipsomania, viz., that, since he is cured, he can take one glass and then stop. He takes it, but he doesn't stop. As a precaution, after the patient has returned to his usual avocation, it is just as well to have him come to the office first daily, then every other day for a week or so, for his hypodermic of terchloride of gold. Every pains should be taken to impress both the patient and his family with the necessity of avoiding those causes which in his case seem to determine the attack, and of coming to the physician when the prodromata (most prominent among which are indigestion and insomnia) first appear. By taking these precautions, patients often go two years, and even longer, without a relapse. To make a long story short, dipsomania is one of the graver manifestations of nervous exhaustion. The principles that underlie its successful treatment are the same that underlie the treatment of other extreme forms of neurasthenia, viz., rest, forced feeding, and tonics, with proper care after recovery to forestall a recurrence of the attack.

A Sensitive Soul.—A physician of Ubeda, in Spain, recently committed suicide because his treatment of a case under his care was disapproved of by two consultants who were called in.

Clinical Department.

ABSENCE OF THE RECTUM—DEATH OF THE CHILD IN FIFTY SIX DAYS.

By W. E. BALDWIN, M.D.,

NEWARK, N. J.

THE following case of congenital absence of the rectum, which came under my observation recently, may be of interest, owing to the age to which the child lived :

On August 29, 1891, I was called to see an infant, female, five days old, which had had no passage from its bowels. Soon after birth it had vomited what was undoubtedly meconium. On examining the child the anus appeared normal, but I was able to pass a probe only about one quarter of an inch. The child had nursed and slept as any healthy one would. I advised an operation, which was consented to by the parents. On September 4th I operated upon the child, endeavoring to reach the gut through the perineum, but was unsuccessful, the gut being too high up. I spoke to the parents regarding a colotomy or laparotomy, but they absolutely refused to allow either. The child recovered rapidly from the operation, still taking the breast every two hours and sleeping naturally. On September 11th, the child still being in good condition, another attempt was made to reach the gut through the perineum, still with no success. The child readily recovered from the operation, nursing and sleeping naturally. On September 16th it vomited for the first time, the vomiting lasting for a few hours only. The child then began again to nurse every two hours, and continued apparently healthy and in no pain until October 13th, when still another unsuccessful operation was performed. On October 15th the child was very restless and in much pain, the abdomen was very tympanitic, and there was persistent vomiting of dark stercoraceous matter. This continued until October 20th, when the child died, being kept under the influence of opium meanwhile.

Post-mortem examination showed marked dilatation of the stomach and intestines, the ascending, transverse, and descending colon being filled with fæces. The descending colon ended in a blind pouch just above the sacral promontory, the rectum being merely a fibrous cord. There were also marked evidences of peritonitis. This child lived to the age of fifty-six days, and nursed regularly about every two hours for forty-six days.

EUGÉNOL.

By LOUIS C. PETTIT, M.D.,

NEW YORK.

THE chemical, physical, and therapeutic properties of eugénol having recently been given some attention by the profession, I may be permitted to recall some investigations made by myself some years ago, and to add some more recent observations on the subject.

The volatile oils from cloves, pimento, and the leaves of myrcia acris were found to contain respectively seventy-two, sixty-one, and forty-one per cent. of rectified eugénol.

Throughout the entire experiments the acid prepared from the three oils gave similar reactions under the same treatment, and their physical properties were alike. The acid was obtained most easily from the oil of pimento, but most economically from the oil of cloves.

The original investigations of Ettling and Bonastre (Gmelin's "Handbook of Chemistry") almost exhaust the chemical and physical properties of the acid, but a few practical points on its preparation may be of some value.

The oil of cloves should first be neutralized with a strong solution of potassic hydrate; the fragrant odor of the hydrocarbon will manifest itself when the point of saturation has been reached. The hydrocarbon can be freed from the mixture by distillation and the remaining solution of eugénate of potassium decomposed by the addition of sulphuric acid, when the eugénol will separate and float in brownish-colored oily-like globules and may be drawn off with a pipette, washed, and dried over sulphuric acid. The resulting crude eugénol rectified by distillation from a glass retort on a sand bath, gives a clear oily liquid, having when fresh a pungent odor similar to that of cloves, distilling at a temperature of 470° F., and having a specific gravity of 1.0785 (sp. gr. taken from the acid prepared from the oil of bay).

Former and more recent investigations have convinced me that eugénol has very decided and active therapeutic properties. Applied locally to the skin it first produces a burning sensation, this being followed by some local anæsthesia; applied to carious teeth it relieves pain when due to exposure of the nerve.

The eugénate of potassium when taken internally in a dose of 5 gr. produced active purgation and caused griping pains

It is highly probable that the rectified acid has antiseptic and local anæsthetic properties.

WARD'S ISLAND, N. Y.

Progress of Medical Science.

The Germ Theory of Diphtheria from the Therapeutic Point of View.—According to the *Bulletin Général de Thérapeutique*, October 30, 1891, Dr. Jacques, of Marseilles, promulgates the following doctrine: While diphtheria is due to a specific germ from which emanates toxic properties, causing various disorders in their journey through the economy, the germ itself exists only in false membranes, and does not penetrate the blood or organs. The mouth and false membranes contain other micro-organisms beside the specific diphtheritic germ. Gargles are recommended every hour, first of perchloride of iron in solution, followed by washing the throat with warm water containing three parts boracic acid to every hundred parts water; and the alternate hour, a gargle of carbolic solution, 1 to 100, without washing the throat afterward. For very young children powders may take the place of gargles.

The Frequency of Gall-Stones.—Dr. Bollinger's experience in the Munich Pathological Institute from 1881 to 1886, and his further study of the question, has resulted in the following statistics as to the frequency of gall-stone disease. In Munich, 5.4 per cent.; Dresden, 7 per cent.; Basel, 8.8 per cent.; Strasburg, 12.3 per cent., or for the whole of central Europe, about 7 per cent.; so that out of every fourteen adults one is affected with gall stone. The proportion of men affected stands to that of women as two to five for the first three cities, while the Strasburg statistics show that women are affected five times as frequently as men. The explanation of this is found in faulty dress, laced corsets, sedentary life, restricted muscular work, pregnancy, etc., and as many of these conditions are more prominent in advanced years, we find that from twenty-five to thirty-five per cent. of women over sixty years of age are affected with gall-stones. In the post-mortem of forty-five women with gall-stones there was found seventeen times, or in forty per cent., a constricted liver. The fact that in women under thirty years of age gall stones are four times as frequent as in men, speaks more for the pathogenic influence of dress than of pregnancy; that corset-lacing much earlier and much more intensely works than does the gravid state. The influence of age upon the existence of gall-stones is shown by the following figures: From fifteen to thirty years of age, 2.7 per cent.; thirty-one to sixty years of age, 5.9 per cent.; above sixty years of age, 15.2 per cent. Among constitutional influences, those of disturbed circulation are made prominent, especially a retarded blood-current, which leads to decreased secretion in the bile-passages, and thus to stagnation and thickening of the bile.—*Münchner Med. Woch.*

Surgery of the Brain.—In a memoir on "Surgical Intervention in Lesions of the Brain," Dr. Laurent believes he can claim: 1. That success follows operation in a certain number of brain lesions. 2. Hydrocephalus can, however, be regarded as incurable in the great majority of cases. 3. Cerebral abscess is frequently cured by operation. 4. Traumatic epilepsy in general justifies trepanning. This is shown to be less effective in Jacksonian epilepsy. 5. As regards tumors, operation is scarcely indicated, excepting for those which are small, well defined, and superficially situated. 6. Excision is the treatment by choice for encephalocele of medium volume. As a general conclusion the author says surgical intervention applied to brain lesions cannot ameliorate in a marked way, or cause to disappear, with rare exceptions, any but those which are superficial and limited.—*Le Scalpel.*

Fraenkel's Pneumococcus in Suppuration Processes.—Dr. Nannotti's observations go far to prove that the pneumococcus can give rise to true abscess in connective tissue, either before, during, or after the evolution of a pneumonia. The author relates four instances: one of abscess of the submaxillary region, one of the mastoid region, one of the tissue surrounding a tooth, and one of the perineum. The pus was carefully collected and found to contain only diplococci, and cultures showed the only micro-organism present to be that of Fraenkel. Eperiments on guinea-pigs showed all the special changes caused by the pneumococcus, of which the encapsulated appearance was typical.—*Il Morgagni.*

The Pathogeny of Congenital Hydrocele.—Dr. Verneuil presented a communication to the *Société de Chirurgie* which aids in the solution of the much disputed origin of the fluid in congenital hydrocele. Anatomically it is well-known that there is a communication between the cavity of the vaginalis and the peritoneal cavity, and clinically the tumor is reducible, but it has never been definitely determined whether the accumulation of fluid takes place first in the cavity of the tunica vaginalis or only enters it secondarily from the peritoneum. The author has long been of opinion that the liquid was of peritoneal origin. The patient who is the subject of the present communication was a strong man, twenty-five years of age, having but one testicle. The day following an unusual effort he noticed that the scrotum was enlarged and came to the hospital with a voluminous scrotal tumor, which was readily reducible. It was found that the abdomen was considerably enlarged and dull on percussion. Further examination discovered the presence of ascites and the existence of cirrhosis of the liver. In this case then the ascites had penetrated into the scrotal sac and produced a hydrocele of the variety called congenital in a man who since birth had been a monorchis. The peritoneal origin of the fluid was beyond doubt, and the case favors the theory of this origin for all congenital hydroceles.—*Gazette des Hopitaux.*

Dermatitis from the Use of Resorcin.—Dr. Ravogli says that resorcin is not entirely free from the danger of causing dermatitis when externally applied, and that while poisoning in man from its internal use has not yet been reported, decided and severe symptoms are produced by large doses. The local action varies according to the strength of application. In one to two per cent. it affects the epidermic cells, rendering them slightly stained, dry, and carnefied. In ten to twenty per cent. it macerates and destroys the epidermis, causes inflammation of the papillary layer with formation of blisters, purulent discharge, and by obstructing the meatus of the ducts of the sebaceous glands causes pustules. A number of cases are cited showing the tendency of resorcin to produce dermatitis not only in strong application but also in weak. Ointment containing ℥ ss. to the ounce produced swelling of the whole face, neck, and scalp, with œdema of the eyelids, and the production of bullæ in a number of cases. One application of a solution of ʒ ss. to ℥ iv. to the scalp of a physician with seborrhœa caused such an acute dermatitis of the whole head and neck that the gentleman could not leave his room for three days.—*Cincinnati Lancet Clinic.*

A New Remedy for Rheumatism.—According to the *Lyon Médical*, October 25, 1891, Dr. Betchine, of St. Petersburg, has made special studies in reference to *ephedra vulgaris*, a plant much esteemed by Russian peasants for its anti rheumatic qualities. The bark and the root the observer found efficacious in acute articular rheumatism with high fever. In chronic rheumatism its most favorable action was merely a slight temporary amelioration. Unless fever is present the drug is not especially useful.

The Bromides and Increased Susceptibility to Infection.—In the *Mercredi Médical*, October 21, 1891, Dr. Féré takes up the assertion that patients undergoing bromide treatment are more susceptible to infection than others, particularly to the influence of Koch's bacillus. Upon this latter point there are no positive clinical evidences within the author's personal observation, yet during epidemics of pneumonia at the Bicêtre those persons under the influence of bromides proved most vulnerable. Animals inoculated with tuberculine virus after large doses of bromide began to lose ground immediately and soon died.

Bodily Weight in Mental Disease.—Dr. Fürstner, in the *Deutsche Arch. f. klin. Med.*, p. 273, calls attention to loss of weight in certain period psychoses without loss of appetite or sleep, and not due to excessive muscular movements. Like albuminuria and rise of temperature, this loss of weight is evidently the result of some central influence. The chemical substratum is as yet unknown, as well whether this loss in bodily weight exists in psychoses other than periodic mania or melancholia.

Propagation of Insanity and Allied Neuroses.—It is estimated by Dr. Strahan, in the *Journal of Mental Sciences*, July, 1890, that while the number of the insane has only slightly increased during the past few years, deaths due to diseases of the nervous system in general have increased fifty per cent. within less than twenty five years.

An Inquiry Into the Blood and Urine of the Insane.—In the *Journal of Mental Sciences* for October, 1890, Dr. J. Smith notes the lessened proportion of hæmoglobine among the insane, this peculiarity being greatest in cases of secondary dementia. It is not particularly marked in melancholia, general paralysis, and epilepsy. In spite of diminution in hæmoglobine and red corpuscles the specific gravity of the blood is increased, indicating abnormal density of the plasma. The quantity of urine is great in general paralysis, reduced in secondary dementia, about normal in other forms of insanity, and apparently lessened in melancholia. Urinary solids exist abundantly in general paralysis, and are much diminished in secondary dementia, the other forms of mental disease presenting nothing unusual in this particular. Uric acid is excessive in general paralysis, epilepsy, and dementia. There appears to be a slight excess of phosphoric acid in epilepsy.

Calomel in Eclampsia.—Dr. Smits reports, in the *Frauenarzt* for September, 1891, the case of a young pregnant woman, nineteen years old, who had a series of convulsions followed by profound coma. The urine was very scanty and albuminous, and the skin was dry. Pilocarpine was tried without any good results, and it was then determined to give an active purgative. For this purpose Dr. Smits gave a large dose of calomel, which caused about twenty stools, containing many uric acid crystals. The patient recovered completely, and gave birth, six days later, to a dead fœtus.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, December 12, 1891.

OVERCROWDING IN OUR CITY ASYLUMS.

IN the four insane asylums of the city and county of New York there are now 5,134 patients. The normal capacity of the buildings of the asylums is 4,089, hence there are over 1,000 patients crowded into wards already filled. Every year there is an increase of admissions, over deaths and discharges, of about two hundred and twenty patients, and this is the rate which has been steadily maintained and will continue in the future. To meet this increase there has recently been built a new pavilion on Hart's Island, and two new pavilions are being constructed on Ward's and on Blackwell's Island. The latter structures, however, will not be completed for a good while, and one of the old buildings formerly used for patients has been condemned. so that there is very little relief yet afforded, or in immediate prospect, for the overcrowded asylums.

Two plans for securing such relief are suggested by Dr. A. E. Macdonald in his report on the New York City Insane Asylums for the year 1890. One is to secure the old Emigrant Buildings on Ward's Island. These belong to the State, but as New York City, besides supporting its own insane, pays nearly one-half the tax for supporting the State institutions, it would be reasonable and just for the buildings to be given the city at a very low figure. The other plan is to enact a law putting it in the power of the Commissioners of the Sinking Fund to issue bonds for the erection of public asylums, just as is now done for school-houses and armories. Dr. Macdonald evidently looks upon this plan as the most feasible, and it is surely a more radical solution of the problem. It will occur to the taxpayer, however, that in time the city may get tired of paying for supporting two sets of asylums, and the question will come why the State should not take care of our city insane as long as we pay for it.

Dr. Macdonald calls attention to the interesting fact that the rate of increase of insanity in the city asylums continues about the same, and he argues that the idea that insanity is increasing beyond the general rate of population is ill founded. Nevertheless, we are confronted with statistics which show that in the population of this city one in every three hundred is insane, and that with the forty thousand annual increase in our city population one of every one hundred and seventy-five must be sent to a lunatic asylum. Or, to put it in another way, the growth of our insane population is about one-third faster than that of our total population. There is, however, some comfort in knowing that this rate is not increasing, but rather the reverse.

THE REPORT OF THE SURGEON-GENERAL OF THE ARMY.

IN 1890–91, the Army Medical Department cost our government about $215,000. With this sum of money the medical and surgical wants of twenty-five thousand men were attended to, and one hundred and fifty permanent or temporary posts were supplied with medical officers. We are told that the expenses of the coming year will be very much less. The sick rate per 1,000 during the year was 42.71, which means that over four per cent. of the soldiers were sick all the time, the duration of each individual sickness being about fifteen days ; the death-rate was 8.69 per 1,000. These rates are rather higher than those given for the armies of Great Britain, Prussia, and Austria.

With regard to the medical service, we note that forty-four candidates appeared for examination before the Medical Board, and five were found qualified.

The Army Medical Museum continues to grow, having received during the past year 964 specimens, making a total of 30,241. One of the interesting additions is the operating-table made for François Magendie in 1831, and used by Claude Bernard.

The Library has added during the year 4,083 books and pamphlets, making a total of 155,321 now on the shelves. Vol. XIII. of the Index Catalogue is well advanced.

We observe that Surgeon-General Sutherland and his assistants are making praiseworthy efforts to introduce a system of identification of deserters. Work in this direction was begun April, 1889, and despite many difficulties and drawbacks much good has already resulted ; 34 recruits have been identified as deserters, 626 as ex-convicts, and 16 as frauds of minor grades.

MEDICAL MEN AS MAYORS.

SAYS *The Lancet :* "The detractors of the medical profession, and those who love to represent it as losing influence, should take into their consideration the remarkable list of medical mayors which we published last week. The following fourteen towns have chosen members of the medical profession to fill the civic chair for the ensuing twelve months : Brighton, Bedford, Lymington, Manchester, Barnsley, Bury, Stratford-on-Avon, Bridport, Chichester, Saffron Walden, Montgomery, Yeovil, Bristol, and Edinburgh. Never before now has a medical man been a Lord Provost of Edinburgh. Now he is not merely a medical man, but an anatomist of standing, and one learned above most in the sanitary side of medicine. Not the least instructive feature in the above list is the illustration it affords of the fact that one man can do so many different things well, and in a way to gain distinction among his fellow-men."

The more rewards a profession offers, the higher will be the class of men who enter it, and we trust that in

time it may be possible in this country for a physician to attain political honors without loss of dignity or self-respect. At present it is rather difficult. Since the early days of our country there has never been a medical man of acknowledged pre eminence who has held a great public office, except possibly a governorship.

SICK PAY INSURANCE FOR NURSES.

Next to physicians, or perhaps even more than physicians, nurses are most exposed to the contagion of disease. There is no greater protection against disease than a good physical condition, in which the stomach craves and digests food, the intestines, the kidneys, the skin, and the lungs remove waste products promptly, the liver elaborates the crude nutrient material into the finished product ready for use in construction and repair, and secretes in abundance the antiseptic bile; and, in short, the whole economy acts as one compact and well-disciplined army, with all its branches—the cavalry, the infantry, the artillery, and the engineer corps—working in harmony each with the other, and each in its own particular sphere. Bacilli may then attack, and micrococci may marshal their forces in vain, the human citadel is impregnable, and the garrison within laughs at the liliputian host which seeks to do it battle. But let discord enter in, let one or other arm of the service become disabled or insubordinate, then all are disabled, and the besieging forces without soon succeed in gaining an entrance, and the battle within the walls becomes a struggle for life or death, or for the even more to be dreaded imprisonment of chronic and disabling disease.

But, to return to our proposition, there is no better preservative against disease than sound physical health, which itself depends in great measure upon a regular life, a regular time for meals, and a regular and sufficient time for sleep. This the nurse cannot have, yet she (or he) is often living in a disease-laden atmosphere, breathing in pathogenic germs in such numbers that it would tax the strongest organism to resist them. Moreover, the labor of nursing is often excessive and most fatiguing; and who has not learned by his own experience that fatigue or the loss of sleep exposes one most certainly to "take cold," if nothing worse?

Some time ago a mutual aid, or rather a mutual sick pay assurance society, known as the Nurses Royal National Pension Fund, was organized in England, and was most successful from the start. The nurses were quick to see the advantage of membership in an association of the kind which would insure them independence if incapacitated for a longer or shorter period by disease, and in old age, should they attain it. Now a similar society has been organized in this country on the lines of the Royal National Pension Fund. Mr. Burdett, to whom was due in great measure the organization of the English society, spent several weeks here during the past autumn, and was invited to address meetings called for the purpose of organizing similar societies here in New York, Boston, Philadelphia, and Baltimore. Many of the most prominent physicians and laymen in these cities became interested in the work, and now the accomplishment of the desired object is secured.

It was decided to organize the association under the laws of this State, which require that a fund of $100,000 must first be provided for the security of the policy-holders, and this fund was immediately secured through the liberality of Messrs. J. Pierpont Morgan and D. O. Mills. It is intended to raise $250,000 as a permanent fund, which, with what may be received in the shape of annual dues from the members, will be ample to meet all sick payments and pensions. We congratulate all concerned in the establishment of this most useful organization, which, in the hands of those who have it in charge, cannot but prosper. And the thanks of American nurses are due Mr. Burdett for his efforts in their behalf.

News of the Week.

Execution by Electricity.—The sixth execution by electricity took place at Sing Sing, N. Y., on Tuesday last. According to the newspaper reports the victim writhed as usual in the death-chair and four contacts were required during a space of six minutes before death was announced. The current of 1,750 volts was applied for forty-nine and one-half seconds, the remainder of the time being allowed for intermissions, examinations, and discussions. The jury of experts maintained a forced silence as commanded, but the warden volunteered the statement that the execution was as successful as the preceding ones. Experiments will be continued. Kemmler's ghost is no longer lonesome. Next!

Memorial to Scarpa.—On the initiative of Professor Rampoldi, a committee has been formed at Pavia for the erection of a memorial to the celebrated surgeon and anatomist, Antonio Scarpa. It is intended to place the memorial in the public hall of the university, and the unveiling of it next year will be made the occasion of a great academic festival. The memorial space should be triangular.

Death of Dr. Herbert G. Lyttle.—On the first day of December, Herbert G. Lyttle, M.D., died suddenly. Dr. Lyttle, though not eminent in the metropolitan sense, was, however, successful in his way in the community in which he labored. He came from the central part of this State; graduated from the Medical Department of the University of this city, afterward serving as assistant and house physician in Charity Hospital, New York. Early in 1879, immediately after his service at "Charity," he began to practise in this city. To diligence, rectitude, and an intelligent kindliness he owed the lucrative practice he succeeded in making his own in a section of the city where nothing is easily attained. A little over three years ago he left New York to continue his work in Long Island City—a growing town of a mixed laboring population. The high esteem in which he was there held by all classes, of almost all nationalities, was shown by the crowds that reverently thronged into his home on the occasion of his funeral.

Further Regulations for the Care and Commitment of Lunatics.—The State Commission in Lunacy has promulgated more rules for the admission of patients to insane asylums, and for the character and conduct of those having charge of these institutions. The new rules which

went into effect on December 1st, provide that all persons committed to such institutions must at the time of admission be informed by the receiving medical officer of the character of the institution, and of the cause of detention. The second order has for subject the admission of voluntary patients into licensed institutions especially permitted to receive them, as well as committed patients. A blank has been drafted which all such institutions are required to have and furnish for such applications. The text of this is as follows:

"I.....hereby request the physician in charge of the above-named institution to admit me as a voluntary patient. I hereby pledge myself to submit to the regulations thereof, to carry out, or to aid in carrying out, all the directions which may be given for my treatment, and that my conduct will not be prejudicial to the good order and discipline of the institution.

"I do hereby declare that I am aware that the above-named institution is licensed by the State Commission in Lunacy to care for and hold in custody insane patients; that the physician in charge has fully explained to me the character of the institution, and that I am at liberty to depart therefrom at my pleasure.

"I hereby consent that the members of the State Commission in Lunacy may freely visit my apartments on any proper occasion, make such inquiries of me as they may deem necessary, and that I will make truthful answers thereto."

Here follows the signature of the patient demanding admission. To this application is appended a sworn statement of two witnesses, who testify that neither of them is a committee of the person and estate, nor a relative or guardian of said applicant, nor connected with the institution in which he asks to be received. They certify that they have read the application and that they believe the statements therein contained; that they are of the opinion that the applicant is capable of forming a rational judgment as to the disposition of his or her person, and that he or she is also capable of resisting any undue influence. In the third order this rule is strengthened by another, which provides that no voluntary patient shall be admitted to a licensed institution for the care, custody, or treatment of the insane, whose mind is so impaired as to render him or her incapable of forming a rational judgment as to the disposition of his person, or whose will is so weak as to render him or her incapable of resisting undue influence, unless the application for admission is made out in the prescribed form. The commission also announce that no license will be granted to operate or maintain any insane asylum, unless it will be constantly in charge of a well-educated physician, a graduate of a legally incorporated medical college, who must have had at least five years' actual service as a physician in an institution for the care and treatment of the insane. This rule will apply to all future appointments in existing institutions, and the approval of the commission in writing will be required upon the appointment of all assistant physicians, the resident physician bearing the title of physician in charge.

Terchloride of Gold was used twenty years ago by Dr. Hoffman, of New York city, as a cure for alcoholism, and failed.

St. Francis Hospital, Fifth Street, near Avenue B, New York City.—An examination to fill vacancies on the house staff will be held at the hospital on Tuesday, December 29, 1891, at 11 A.M. Applications must be indorsed by a member of the Medical Board and presented to the Secretary, Dr. G. M. Edebohls, 198 Second Avenue.

A Blow at the Dog.—The *Texas Sanitarian* says: "There is one sanitary evil, a source of great danger to human life and happiness, a standing menace to society, which, however, seems never to have occurred, either to our own sanitarians or our law-makers—*the dog*."

Local Remedies for Diphtheria.—Of recently introduced local remedies, two have been highly commended: peroxide of hydrogen and sulpho-calcine. With each of these the writer has saved lives, in cases where the chlorine mixture affected the healthy tissues so strongly as to preclude its use.—*Times and Register*.

Scientific Congresses in Russia.—International congresses of anthropology, prehistoric archæology, and zoology are to be held at Moscow in August, 1892. M. Bogdanow is president of the Organizing Committee, which includes representatives of the principal civilized countries. Thus England is represented by Messrs. Flower, Ray Lankester, and Günther; France by fifty six members, among whom are Prince Roland Bonaparte, MM. Pasteur, Milne-Edwards, de Quatrefages, G. Pouchet, C. Richet, etc.; Germany by Virchow, Weismann, Rosenthal, Leuckart, etc.; the United States by Messrs. Agassiz, Packard, and Riley.

Drugs and Silks.—The department of pharmaceutical preparations, medical supplies, etc., has been for some unknown reason tacked on to the silk department of the Columbian Exposition. It is hoped this important branch of manufacture, with allied matters, such as surgical instruments and appliances, may be given an exhibit by itself under a competent head, and steps in that direction are being made.

Doctors' Wives at Medical Societies.—At the meeting of the Practitioners' Club, of Chicago, October 26th, the ladies present were the prominent feature and the subject of discussion, taking a fair share in the entertainment and post-prandial discourse. From their many assertions it would seem that the life of a doctor's wife is full of special cares and deprivations. Dr. Henry M. Lyman presided.—*Chicago Medical Recorder*.

A Venereal Congress.—A project is now under discussion by different boards of the Paris municipal government to establish an International Congress to consider questions connected with prostitution and the limitation of venereal diseases. It is proposed to hold the congress in Paris in 1893, and to invite medical men, lawyers, sanitary officials, and political economists.

Stites's Surgical Criterion for Cancer.—Dr. John H. Brinton has put into practice at his surgical clinic at the Jefferson Medical College a new test for cancer, proposed by Mr. H. J. Stites, of Edinburgh. The method, as given by Dr. Brinton, in the *Medical News*, October 31st, is that which was furnished him by Dr. John Chiene, of the Royal Infirmary of Edinburgh, and reads as fol-

lows: "1. Excise the mamma. 2. Wash thoroughly in water to remove blood. 3. Place in a five per cent. solution of nitric acid (B. P.) for ten minutes. 4. Wash in cold water for five minutes. By the time these procedures are executed the axilla is cleaned out and the vessels tied. The mamma is now examined; the carcinomatous structure appears a dull white, like the eye of a boiled fish, the healthy tissue translucent. When any such reaction is seen additional tissue should be removed at the corresponding point. In removing the carcinomatous breast, Professor Chiene directs that its relations to the circumferential tissues should be marked by the knife, so that after the test has been applied to the mass excised the situation of any outlying, unremoved diseased areas can be fixed."—*Journal of American Medical Association.*

Society of the Alumni of Charity Hospital.—Officers elected for 1892: *President*, Dr. D. Bryson Delavan; *Vice-President*, Dr. Walter Lester Carr; *Secretary*, Dr. Carter S. Cole; *Treasurer*, Dr. A. T. Muzzy.

A Dentist in Aix-la-Chapelle has been sentenced to nine months' imprisonment for pulling out all a woman's teeth while she was under anæsthesia. She wanted only one pulled.

Reviews and Notices of Books.

Diagnosis and Treatment of Hemorrhoids and Other Non-Malignant Rectal Diseases. By W. P. Agnew, M.D. Second edition. Pp. 148. San Francisco: R. R. Patterson. 1891.

This is a practical little book, although it is not without serious faults. The arrangement of topics is not a good one, as the introductory chapter should treat of methods of examination. Nearly one-half of the volume is devoted to the treatment of hemorrhoids by carbolic acid injections, of which the author is an earnest advocate. The non-operative treatment of fissure, ulcer, prolapsus, etc., is described under those headings. We note a useful section on flushing the colon, and another on pruritus ani. While there are undoubtedly many useful hints for the general practitioner, the propriety of throwing all surgical procedures into the background is questionable. The illustrations are fair, though Fig. 18 is a little too strong, even for a medical work. "Dilatation" is spelled "dilitation" throughout the book.

Studies in Pathological Anatomy. By Francis Delafield, M.D., LL.D., Professor of Pathology and Practical Medicine, College of Physicians and Sugeons. Vol. II., Part 4, Chronic Bright's Disease. Plates LXXXIII.–CXXXIII. September, 1891. New York: William Wood & Co. 1891.

Our readers are already so familiar with this admirable work that it is unnecessary to add to our former expressions of approval. The present number is unusually interesting, since it deals with a subject of which the author has long made a special study. Professor Delafield's views on renal disease are familiar to generations of students who have listened to his lectures. No man has been more successful in bringing order out of the chaos in which the subject has been involved. Praise of the execution of the drawings is superfluous. With a few exceptions the photo-gravures are beautifully clear and distinct. The accompanying text presents in a lucid though condensed form a *résumé* of the pathology of Bright's disease. The expenditure of so much labor upon a purely scientific work reflects credit not only upon the author, but upon his countrymen, and removes the reproach sometimes cast upon us by foreign scholars—that our profession does not love science for itself alone, but for its practical and financial returns. The superb work, of which this is an important part, will well bear comparison with any previous one here or abroad; in fact it is unique in its way.

Intoxications par le Sublimé Corrosif chez les Femmes en Couches. Par le Dr. Richard Sebillotte. 8vo, pp. 194. Paris: G. Steinheil. 1891.

A very timely treatise on mercurial poisoning from the use of bichloride solution in lying-in women. The volume presents an admirable résumé of the subject, and besides much original investigation, the literature has been carefully scanned, not only for the severe and fatal cases, but for the reports of slight poisonous manifestations. Three colored plates illustrate the erythematous skin lesions often found in mercurial poisoning, and the work will interest the dermatologist as well as the obstetrician.

My Water Cure, as Tested Through More Than Thirty Years. By Sebastian Kneipp, Parish Priest of Worishofen, Bavaria. Translated from the thirtieth German edition by A. de F. 12mo, pp. 268. Edinburgh and London: William Blackwood & Sons. 1891

This book is interesting in its way as showing how disease may be cured by very simple means and by the enthusiastic advocacy of one idea. The treatment is based on the good effects of water applied in accordance with the water cure system, modified by uninportant essentials, and being more or less subservient to mental influences. A parish priest, all simplicity and ardor, with the dogmatism of an oracle, insists upon certain details, which are impressive and convincing to the chronic invalid who is in search of something novel and subjectively effective. Hence the cold douche to different parts of the body with a sprinkling pot, the walking barefoot in wet grass and freshly fallen snow, and the hardening of the body to changes of temperature with the necessary auxiliaries of exercise, care in diet and the administration of decoctions of different harmless herbs at stated intervals and in accurately measured dosage. All these means are doubtless effective in their way, but hardly prepare us for an appreciation of the remarkable cures which abound in the book, which savor more of a miraculous than a scientific aspect.

The Evolution of Life, or Causes of Change in Animal Forms: a Study in Biology. By Hubbard Winslow Mitchell, M.D. 12mo, pp. 453. New York and London: G. P. Putnam's Sons. 1891.

The author gives an entertaining and instructive work in endeavoring to elucidate the problem of the evolution of life from the standpoint of accepted geological development of our planet. Naturally his reasoning is based upon purely anatomical and physiological principles, tracing the original protoplasmic cell through all its evolutions of fish, reptile, marsupial, mammal, ape, and man. He defends the Darwinian theory throughout, and very ingeniously explains the reasons why and how the evolutionary changes took place, in response to developing necessities of condition and environment. The studies to these ends are based upon accepted anatomical and physiological principles, and of themselves, independent of any special theory, are highly instructive, entertaining, and suggestive. Anyone given to these lines of investigation will read the work with rare interest and will be impressed with the wide ranges of study which made the accumulation of the vast array of facts possible, and with the logical skill that has marshalled such facts in the line of legitimate argument. The most curious part of this volume is the final chapter on "Terrestrial and Cosmogonic Prognosis." In it the author declares his belief that man has reached, at least for ages to come, his highest anatomical evo-

lution, that he is virtually in possession of the earth, that all inimical influences to him will eventually be overcome by his prowess, and that the sparsely inhabited regions will be conquered and occupied by him as long as our present planet lasts.

THE PHYSICIANS' READY REFERENCE ACCOUNT-BOOK. Arranged by GIDEON C. SEGUR, M.D., Hartford, Conn.

THIS book has the usual oblong shape of account-books, is substantially bound and very conveniently arranged. At the top of each page are the spaces for the name and address of the patient. The horizontal lines are divided vertically into daily date spaces, as well as spaces for the year and month, together with those for total monthly charges and credits. The credits are made in red and debits in black ink in the space of corresponding date. A page can be used for one or several accounts, although provisions are made for short accounts in the concluding pages. The whole arrangement is exceedingly simple and effective and must recommend itself to every practitioner who must necessarily be his own accountant.

THE COMPARATIVE ANATOMY OF THE DOMESTICATED ANIMALS. By A. CHAVEAU, M.D., LL.D. Second English Edition. Translated and Edited by GEORGE FLEMING, C.B., LL.D., F.R.C.V.S. 8vo, pp. 1084. New York: D. Appleton & Co. 1891.

THE present volume is a translation of the fourth French edition, which was issued one year ago. In it many additions, alterations, and amendments have been made to bring it to the requirements of a standard work. The anatomy of the ass, mule, and rabbit has been incorporated, while the number of illustrations have been increased to more than one hundred and thirty, the page enlarged, and the letter-press adjusted to the requirements of ready reference. This work has long since earned for itself the position of foremost rank in its particular field, and, indeed, stands without a rival in completeness, scientific arrangement, accurate detail, and practical adaptability to the necessities of the veterinary and to the student of general anatomy. It is profusely illustrated and handsomely printed.

A MANUAL OF DISEASES OF THE THROAT AND NOSE, INCLUDING THE PHARYNX, LARYNX, TRACHEA, ŒSOPHAGUS, NOSE, AND NASO-PHARYNX. By MORELL MACKENZIE, M.D. Lond., Consulting Physician to the Hospital for Diseases of the Throat, etc. Two volumes in one. 8vo, pp. 400. New York: W. Wood & Co.

THIS work is so well known to laryngologists and to the general profession, and has been reviewed in one shape or another so often that the latest edition needs but to be announced to be duly appreciated. To such as may not be acquainted with its special merits it may be well to refer to some of the leading features of its make up, and the general scope of its teachings. In a word, the conclusions arrived at may be said to represent an unusually large experience with all the forms of trouble grouped under the particular specialty in which the author, in more ways than one, has made himself famous.

There is a breadth of view of the subject, as well as power of condensation which gives to the book a completeness of range scarcely equalled by any, but certainly not by one of its size. No evidences of hobbyism show themselves by the exclusive adoption of any special form of treatment, but there is evidenced a desire on the part of the author to utilize all the available methods of others and adapt them generously and broadly to a large personal experience. Consequently the constitutional as well as the local methods receive their due share of attention. Especially is this seen in the constitutional diseases, notably syphilis, in which the treatment, both general and special, must necessarily be modified to suit the requirements of special cases. As a disciple of Sigmund of Vienna, the author's views regarding the treatment of specific throat affections are consistent with his methods of practice; but, despite the good results claimed, the doctrines upon which they may be founded will not always go unchallenged.

It is needless to go over in detail the numerous additions and revisions of the present treatise Suffice it to say that the history, pathology, etiology, and treatment of each of the numerous affections are fully yet succinctly given, and nothing is left to be desired for a comprehensive, compact, and complete book on the subjects named. The forming of two volumes in one, aside from lessening the price of the book to the reader, has the additional advantage of increasing its value as a work of ready but comprehensive reference.

TRANSACTIONS OF THE MICHIGAN STATE MEDICAL SOCIETY FOR THE YEAR 1891. Volume XV. Illustrated Pp. 400. Detroit: O. S. Gulley, Bornman & Co.

THIS book is far and away the handsomest volume of "Transactions" that has been issued this year. An engraving of the President, Dr. Lyman W. Bliss, forms the frontispiece. Illustrations are numerous, one valuable article, by Dr. J. H. Kellog, of Battle Creek, on "The Influence of Dress in Producing the Physical Decadence of American Women," having forty excellent plate figures. The Address on Medicine is by Dr. Heneage Gibbes, of Ann Arbor, on "Phthisis." Dr. H. O. Walker, of Detroit, contributes an interesting paper on the "Progress of Surgery." Sections were held on Practice of Medicine, Surgery and Ophthalmology, and Obstetrics and Gynecology. In each department the papers were of unusual value and by men of prominence. The book deserves a place in the library of every man who aims to keep abreast of the times.

WOOD'S MEDICAL AND SURGICAL MONOGRAPHS for October. Contents: "Treatment of the Diseases of Women," by THURE BRANDT; "The Modern Treatment of the Morphine Habit," by DR. A. FROMME; "A Contribution to the Study of So-called Scarlatina Puerperalis," by PROFESSOR DR. RENVERS; "The Influence of Alcohol upon the Organism of a Child: A Pharmacological-clinical Study," by PROFESSOR R. DEMME; "The Diseases of Development," by DR. J. COMBY. Pp. 258. Profusely illustrated. Price, $1; per year, $10. William Wood & Co., Publishers, 56 and 58 Lafayette Place, New York.

OF the five interesting and valuable papers presented in the October "Monographs," the one that will attract most attention, perhaps, is Brandt's "Treatment of Pelvic Diseases," written by himself. The system, which has become famous, is, in short, made up solely of gymnastics. There is no other medication, and yet displacements, new-growths, and inflammations are all cured by the method. It has been in use by the author for almost fifty years, and he presents cases to show that he has had wonderful results. Only within recent years has the profession given the matter the attention it deserved. The article in hand is a complete exposition of the system, with scores of illustrations, making it of easy practical value to any one who may wish to employ it. The remaining articles in the book are likewise deserving of commendation.

TRANSACTIONS OF THE STATE MEDICAL SOCIETY OF WISCONSIN FOR THE YEAR 1891. Pp. 358. Madison, Wisconsin: Tracy, Gibbs & Co.

THE Committee on Publication of the Wisconsin Society has "done itself proud" in issuing this year's "Transactions." The book is handsomely printed, illustrated with excellent engravings, well bound in cloth, and, above all, contains an immense amount of valuable material. There are thirty-three papers by the leading men of the Wisconsin profession. Empyema, Diphtheria, Syphilitic Lesions of the Eye, La Grippe, Massage, Milk Infection, Tuberculosis of the Bones and Joints, and the Eye Symptoms of Brain Disease, are among the interesting topics discussed.

Society Reports.

MEDICAL AND CHIRURGICAL STATE FACULTY OF MARYLAND.

Semi-annual Meeting, held at Rockville, Md., November 17 and 18, 1891.

PRESIDENT, DR. WILLIAM H. WELCH.

FIRST DAY, TUESDAY, NOVEMBER 17TH.

Address of Welcome.—This was delivered by DR. E. E. STONESTREET, of Rockville, who received the Society in the name of the Montgomery County Medical Society; and was replied to by DR. WILLIAM H. WELCH, of Baltimore.

The Bacillus Coli Communis; the Conditions of Its Invasion in the Human Body, and Its Pathogenic Properties.—This was the title of the President's Address, which was delivered by DR. WILLIAM H. WELCH. He began by saying that it might be considered rather remote from the interests of practical medicine to consider this subject; its study might not help diagnosis or treatment, but it was of the greatest interest, and in this case he thought he had something new to communicate. The invasion into the circulation or system of the bacillus coli communis was always regarded as unimportant, and this organism was supposed to have no pathogenic properties; but now we know it has. It has long been known that a great many different kinds of low forms of life are in the fæces; and it has been thought that it was hopeless to try to classify them. Dr. Woodward, of Washington, has studied them very carefully, and has shown that the great mass of the fæces consists principally of low forms of life. He did not classify the different species. It was not suspected that there were any bacterial flora there. We owe to Escherich, of Gratz, the knowledge of the fact that there are certain species of bacteria which have their habitat in the intestinal canal, and are found comparatively infrequently elsewhere. Of these the most important, because the most commonly found, is the bacillus coli communis. In 1885 he made his first contribution on the subject, his studies being based on the examination of the stools of nursing infants. He found it predominating. It is described as a short rod with rounded ends about $\frac{1}{4}$ to $\frac{1}{2}$ the diameter of a red blood-corpuscle; it is plump as compared with the tubercle bacillus. It has very little characteristic in its form. It is like many organisms which we already know. The typhoid bacillus resembles it so closely in its form, that one would not be able by the appearance alone to distinguish them, but they can be distinguished by culture media. It is feebly motile according to some, and non-motile according to others. It grows in various culture media, in bouillon, in gelatine, in agar-agar, and in a roll culture is seen very faintly; the colonies are seen very faintly with the naked eye. The method of study is familiar to all bacteriologists. A sterilized platinum needle is passed into the substance to be examined, and then put into the liquefied agar-agar; this is then rolled horizontally on a piece of ice until the medium is deposited in a thin film on the inside of the tube, which is put in the incubator over night, and the result is a number of small colonies which the speaker showed. Their growth and reaction may be also noticed in milk. Add litmus to the milk, and then inoculate it with pure cultures of the typhoid bacillus and of the bacillus coli communis, and in the former case the milk remains fluid, and in the latter case the milk is coagulated. It is important to know whether this organism, the bacillus coli communis, has pathogenic properties or not. The answer to this is equally important whether positive or negative. In typhoid fever the trouble is we cannot find an animal susceptible to the typhoid bacillus. When an organism enters the body it causes disease, either by infection or by intoxication. Infection is when the organism multiplies in the body, and intoxication is when the organism emits a poison. The bacillus coli communis causes an infection, not an intoxication. In experiments on rabbits, Dr. Welch injected a pure culture of this organism, and the animals emaciated and died in two or three months. At the autopsy it looked as if death was caused by the organism getting into the gall-bladder. The effect seems to be according to the amount inoculated. He came across this organism in a case of pancreatitis. The etiology of this disease, which Dr. Reginald Fitz, of Boston, has so thoroughly written up, is obscure. Cultures were made from this case. It is not a post-mortem organism. When found in the body it is not a sign that it got there after death. At the Johns Hopkins Hospital the autopsies are made soon after death, and thus the danger of post mortem organisms is reduced to a minimum. In this case the abdomen was opened and a large flat knife, which had been heated in the flame, was laid on the pancreas, thus destroying all organisms that might be on the surface of that organ; then the sterilized platinum needle was plunged into the substance of that organ, and the œzes brought up a little speck of substance which was put into the culture medium. In the case just mentioned, in which the bacillus coli communis was found in pure culture, there was a diphtheritic looking condition of the intestinal mucous membrane. The organism probably made its way through the diseased intestinal mucous membrane and thus got to other organs. He had found it in no less than thirty-three of the two hundred and fifty autopsies which he had performed at the Johns Hopkins Hospital. All of these had a lesion of the intestinal canal. All had dysentery and a diphtheritic-looking condition of the large or small intestine. There were hemorrhages, ecchymoses, and typhoid ulcerations. The question to be asked is: "Is the invasion of this bacillus of practical interest or not? does it do harm?" There is no evidence always that it does, but in some cases it seems to. He had had some cases at the hospital of dysentery caused by the amœba coli. In these cases, which were usually fatal, he had found with considerable constancy the bacillus coli communis. It may be a factor of some importance. There are cases in which the organisms do injury. He had seen several cases of peritonitis of late; this is a most common cause of perforation. These were usually without perforation. The peritoneal fluid was examined, and it was found to be a pure culture of the bacillus coli communis. In another case there was a cancer of the rectum and an abscess, and the pus from this abscess contained almost a pure culture of the organism. He had seen six cases in which this organism had caused an infection of the laparotomy wound. In a number of these cases there had been numerous adhesions. It caused fever and prevented union by first intention. It also does harm in the secondary bronchopneumonias. It is caused by some lesion in the intestinal tract. Fränkel found this a common cause of peritonitis in one-third of his cases. The streptococcus and staphylococcus were also found.

DR. ERNEST BLACK, of London, thought that more and more light was needed on the precise nature of the products of decomposition formed by the bacilli. He asked Dr. Welch if a pure culture of the bacillus coli communis could be absorbed by the healthy mucous membrane.

DR. WELCH replied that this organism is not known to produce injurious chemical substances. Lactic and acetic acids are produced in the fermentation of milk. We have very little work on the subject, but he does not believe absorption takes place.

The Rest Cure and Cases to which It is Applicable.—DR. GEORGE J. PRESTON read a paper on the above subject. He referred to Hodge's experiments and the change produced in nerve-cells by stimulation, and the restoration of these cells by rest. Hence the rest cure has a physiological basis. The natural relief of pain is rest. The necessary things in a rest cure are isolation, rest, forced

feeding, and artificial exercise. Isolation is very important. No one but the doctor and nurse should see the patient. The patient should be removed from home and the above rules followed, with attention to the diet, baths, and the use of electricity when indicated. It is not easy to say to what class of cases this treatment should be applied. There is a distinctive and easily recognized class of cases to which this treatment applies.

Dr. T. A. Ashby, of Baltimore, thought the rest treatment was very important. He referred to a number of cases in his own practice. The ovaries are removed too often. He agreed with Dr. Preston when he said that the surgeon might just as well remove the testicles for seminal emissions as remove the ovaries of a neurasthenic.

Dr. Robert T. Wilson, of Baltimore, said he had had the same kind of experience in his own practice, and related a case. He seconded all that he said.

Dr. Roger Brooke, of Oakdale, was very glad to hear the paper, and thought such work was productive of much good.

Dr. Black thought that forced feeding was of the greatest importance. There were many cases in which the patient did not begin to improve until forced feeding was used. He especially recommended peptonized enemata.

Dr. Welch said that the work of Hodge was decisive. The prolonged irritation of a nerve causes a change in its cells. Prolonged functional disturbance may cause an organic disease. Thus cases of prolonged neuralgia from a tooth may cause an organic disease of that nerve, and the blood-vessels would thicken in their walls. Dr. Putnam, of Boston, has shown that reflex irritation will cause organic disease of the nerve.

Typhoid Fever.—Dr. Edward Anderson, of Rockville, read this paper. Every case came from the same cause, whether long or short, mild or severe. If short, it is usually called malaria or gastric fever. This is usually a mistaken diagnosis. He would call it headache fever, for headache is always present, while all the usually described symptoms may be absent. It is a scourge everywhere, but it is particularly prevalent in Rockville. He attributed this not so much to the drinking-water as to the clay soil, which becomes dry and is carried about as dust. This soil is saturated with the typhoid poison. He quoted several cases.

Dr. Ashby thought it was usually caused by drinking-water. It was strange we did not have this disease more often than we do.

Dr. Preston said one proof of the fact that water usually caused typhoid fever was that it was much less common in the cities than in the country. Milk may also be a cause. He had noticed that the disease would be mild one year and severe another. He found that the cases that came late to treatment were the ones that were fatal. He preferred egg-white to milk.

Dr. Henry U. Onderdonk, of College of St. James, said that he had examined a large number of specimens of water for physicians of that region, and he had found chlorides, nitrites, nitrates, and thought that such water must contain the typhoid bacillus.

Dr. J. McP. Scott, of Hagerstown, said that correction of defective drainage would stop the disease, even when the drinking-water seemed at fault.

Dr. Welch thought it was important to study the cases which differed from the usual forms. Much harm had been done by the text-books in describing this disease. There are cases without the usually noted symptoms, and cases with them. The cases of constipated typhoid fever are by no means the most favorable. Some cases assume the disguise of Bright's disease. The continued fever seems to be the most common symptom to all types. Harm has been done by setting up the type of typho-malarial. The two diseases are combined, but not often. It is used to cover up the ignorance of the physician. We have means of recognizing malaria by examining the blood. If the malarial organisms are present we have malaria; if they are absent, then we have no malaria. Typhoid fever is a disease which the physician should have in his mind when he is called to attend a case of continued fever. He related a case of walking typhoid fever which went to a physician for some supposed trouble, and one day dropped dead on the street. It is a tricky disease, and may assume all sorts of disguises. It is a novel thing to hear the ground hypothesis advocated in this country at the present day. The drinking-water is so generally considered the cause, especially in the opinion of Americans and English, that the ground hypothesis is in the background. Pettenkofer, of Munich, who is a thorough hygienist in its strictest sense, is the leader of the ground hypothesis, while the bacteriological school of Koch is a strong adherent to the drinking water theory. Typhoid fever can originate in various ways. It generally comes from the drinking-water, but it may not be impossible for it to develop in the way Dr. Anderson has said. Uffelmann found that it lived in the earth a year. The typhoid bacillus does not form spores, but it is very resistant. It may be taken in with the dust. The ground hypothesis cannot be denied entirely. Uncooked food may possibly cause it. Impure water may infect without being drunk; it may contaminate the vessels in washing them. It is well known that milk will cause the disease. The bacillus does not get in from sewer-gas, but families returning to a house that has been closed for a long time may get the disease, from that fact that the water in the drains and water-closet traps has evaporated, and any dried matter in these pipes containing among other things the typhoid bacillus, may be wafted into the house by backward currents of air and cause the disease. In such cases the places just left, usually a summer resort, is blamed. In Munich the introduction of good water had no effect, but improvement of the drainage caused the disease to disappear at once. In Hamburg the reverse was true. The typhoid bacillus is not choice in what it eats. It will grow on almost anything. The fact that this bacillus grows readily in milk is no reason why we should deprive our patients of milk. As the bacillus will grow on almost anything, we should have to starve our patients in order to protect them. Besides, it is not so much keeping the organism from getting into the body as to keep the body strong enough to throw off attacks of the bacillus. There is no substance which contains so much nutritive matter as milk, and nothing is better than it in typhoid fever.

Second Day, Wednesday, November 18th.

Appendicitis in the Female, with Report of Two Cases.—Dr. T. A. Ashby, of Baltimore, read this paper. He thought that appendicitis occurred frequently in the female when it was not recognized, because the pus escaped by the vagina or in other ways. He related several cases.

Dr. Welch said that he had had some little experience in this disease. The subject is interesting and little investigated. The reason it is supposed to be so much more common in the male than in the female, is because statistics are not properly collected. This is difficult. There are more males than females in hospital. Like cancer of the stomach, it is no more common in males than in females. There are some causative differences in the two sexes. One case which he had seen at the hospital was one of extra-uterine pregnancy. It was tubal. The diagnosis had not been made before she entered the hospital The third week the sac ruptured into the peritoneal cavity, and there was a profuse hemorrhage. The patient was better in a week. The diagnosis was made by withdrawing with a sterilized needle a little fluid from the peritoneal cavity, and this fluid, which was blood, was found to be a pure culture of the bacillus coli communis. This showed a perforation of the intestinal canal, for how else could this organism get in? The diagnosis was confirmed subsequently. This was the only

thing about the case that led to a suspicion of appendicitis. An operation was decided on and laparotomy was performed. As soon as the peritoneal cavity was opened the blood spurted out seven inches high and two inches thick. The patient died almost at once.

The autopsy showed an appendicitis and diffuse peritonitis. There had been a tubal pregnancy on the right side, which had ruptured. The diagnosis was made with the microscope. The appendix was adherent to the sac on the right side, and this is probable. It is probable that the appendix was ruptured in rupture of the sac. This is interesting, the diagnosis resting on the bacteriological examination, and the sudden death. The patient had shortly before had a hemorrhage into the peritoneal cavity, the tension was excessive which compressed all the viscera and the blood-vessels. This is different from the collection of an ascitic fluid, because that is a gradual accumulation and the vessels have time to accustom themselves to the change. The volume of blood in this case was diminished by the hemorrhage. The abdominal vessels can contain all the blood of the body, and in this operation the pressure being suddenly let up, the blood was drawn from all other parts of the body and the circulation could not be kept up. In these cases a salt solution injected into the blood-vessels does as much good as blood, and is not so dangerous. This patient died of "hemorrhage into her own vessels."

A still more interesting case was that of a negress, aged twenty-one, married three years; had had two miscarriages, and developed during the last six months great pain and weakness in the back and side, and leucorrhœa. She was not incapacitated for work. She came to the hospital. Examination showed that the cervix was low down and enlarged, os patulous. On the left side was a fluctuating mass as large as a lemon; on the right there was nothing. Diagnosis, pyosalpinx of the left side. Laparotomy was performed, and left ovary and tube and appendix removed. On the left side there was a pyosalpinx. The fimbriated extremity was obliterated, ovary not involved. On the right there was no pyosalpinx, but evidences of disease. The contents of the right Fallopian tube was muco-purulent. The vermiform appendix was adherent to the right tube. A culture made from the pus in the left tube was negative and sterile. This is the usual result, and it is surprising. These cases are gonorrhœal, and later on the organism disappears; still it does not grow in the usual culture media, so that when we find such a case where there is no growth, we consider it gonorrhœal. He made cultures from the right Fallopian tube and found small cultures; they were the streptococcus pyogenes aureus, the most virulent of the pus-producing organisms. He thought this was a case where the inflamed vermiform appendix had set up by adhesion a salpingitis. This is another cause added to the list of causes of this trouble. The finding of the streptococcus makes the prognosis worse than if other forms were found. It is the organism of puerperal fever and septicæmia.

This patient was isolated and a drainage-tube was not inserted, as he considered it as a source of danger. The temperature went up to 104° F., and she died soon after the operation. The autopsy showed a duodenal ulcer, an unexpected complication. There may be a co-relation between the ulcer and this case; he had seen three others like it, but could not trace the connection.

Laparotomy for Removal of a Purulent Tumor of the Right Ovary.—This was read by Dr. Robert T. Wilson, of Baltimore. This was not a suppurating cystoma of the ovary, but an abscess of the ovary *per se*. He operated with good results, and laid great stress on the use of the drainage-tube or iodoform tents to facilitate the discharge of the pus, etc.

Dr. Ashby said this was an interesting case. They are not always easy to diagnose. He had had several, but in none was the tumor as large as an infant's head, as narrated by Dr. Wilson.

Dr. Welch had seen several cases of abscess of the ovary, and agrees with Dr. Wilson that it is very rare. In pelvic peritonitis the organisms do not have to penetrate, but it is difficult for the organisms to get into the ovary. Its tunic is so thick, and the different tissues oppose the invasion of bacteria, and the stroma of the ovary is not prone to suppurate. He mentioned a case of ovarian abscess from abscess of the rectum, and recalled a case of genuine abscess of the ovary. They are not so very uncommon, nor are they very common. They are not easy to recognize when the tumor gets as large as Dr. Wilson's case. He thought the drainage-tube was called for in this case, but the chances of union by first intention were opposed by the use of the drainage-tube.

Occupation and Disease; with Special Reference to the Connection between the Inhalation of Dust and Pulmonary Disease.—Dr. William B. Canfield read a paper on this subject. The substance of this paper was to show the dangers of dust in mills, mines, factories, and in other closed places where dust is present in excessive amount. This dust is dangerous because of its amount, its poisonous nature, or because it may make a way in the lungs for the invasion of the bacillus tuberculosis and other organisms. He suggested proper ventilation and means to carry off this dust.

Dr. Preston had seen several cases of lead poisoning among a number of stone-cutters employed in the same shop. He found it due to a certain polishing powder which the men used, and which they inhaled in sufficient quantity to get its constitutional effects.

Dr. Welch referred to a case of anthracosis in which he had found dust not only in the lungs, but also in the liver and other organs. He thought it was often there, but was overlooked.

A Case Illustrating the Diagnosis of Extra-uterine Pregnancy, and the Difficulty of Producing Abortion.—Dr. J. E. Michael, of Baltimore, related a case of a woman, aged twenty-two, unmarried, who had been treated for suppression of menses, first by drugs, later, locally, in view of a muco-purulent discharge from the cervix. Local treatment in applications to the uterine cavity of Churchill's tincture. This was done fifteen times, the applicator having been passed four and a half inches. Dr. Michael diagnosed pregnancy in sharply anteflexed uterus. Natural labor proved the correctness of the diagnosis.

Dr. Stone, of Washington, in discussing extra uterine pregnancy, related several cases and asked where pregnancy occurred. A rupture through the tube into the broad ligament was called an interstitial pregnancy.

Dr. Welch related a case of a couple who had been married fifteen years without children, when the wife became pregnant. Everything seemed to be going on well, when there was suddenly pain, collapse, and symptoms of internal hemorrhage. As she was the wife of a well-known physician, many were called in. She passed some material by the vagina. Some thought it was a case of miscarriage, while others (Thomas and Lusk) said it was extra-uterine pregnancy. Dr. Welch examined the matter with the microscope and it showed decidual matter, but no chorionic villi. He decided it was a case of extra-uterine pregnancy.

Dr. Stone asked if it was usual for hemorrhage to occur at the fourth month outside of the sac, after the fœtus is two weeks or a month old; he did not know what caused a hemorrhage and from what artery it came. There was no rupture of the sac.

Dr. Welch said a rupture of the tubal sac is common. He has never seen such a case where hemorrhage occurred and there was no rupture. Not many years ago these cases would have been simply called hæmatocele. Probably most cases of so-called hæmatocele are really extra-uterine pregnancy.

Notes on the Use of Codeine.—This was read by Dr. A. K. Bond, of Baltimore. He advocated its use in gastric irritation, in the sleeplessness of old age, and in

phthisis. The advantages are, it does not have to be increased and there is no danger of forming the habit as with morphia.

This paper was discussed by Drs. Canfield and Stone, of Washington; Anderson, of Rockville; and Wilson, of Baltimore.

A Case of Elephantiasis of the Scrotum.—Dr. Randolph Winslow related the case with operation and successful results. It was discussed by Dr. Welch.

Early Diagnosis and Operation in Osteo-sarcoma of the Lower Bones.—Dr. Charles E. Stone, of Rockville, read this paper and related three cases well illustrating his subject. It was discussed by Drs. J. W. Chambers, of Baltimore; E. E. Stonestreet, of Rockville; and Welch, of Baltimore.

Report of Fifty Consecutive Operations for Cataract.—This was a paper by Dr. R. L. Randolph, of Baltimore. It was discussed by Drs. Muncaster and Belt, of Washington, and Harlan, of Baltimore.

Correspondence.

EN ROUTE TO THE RIVIERA.

(From our Special Commissioner.)

OBJECTS OF THE "RECORD" HEALTH TOUR—NEW YORK TO LONDON IN ONE WEEK—CORDIAL RECEPTION IN LONDON—MR. ERNEST HART'S COURTESIES—SIR DOUGLAS GALTON AND SIR EDWARD WATKIN, THE SANITARY EXPERTS—INTERVIEW WITH SIR MORELL MACKENZIE—BRIGHTON DURING THE HEIGHT OF THE SEASON—PARIS—MR. BLAINE'S LETTER—CONFERENCE WITH MR. WHITELAW REID—AMERICAN PHYSICIANS IN PARIS—DR. WARREN BEY—DR. PRENDERGAST, LORD LYTTON'S PHYSICIAN—AMUSING EXPERIENCE WITH A RECENT GRADUATE—THE EDITOR OF THE PARIS MEDICAL JOURNAL—TALK WITH CHARCOT.

Paris, November, 1891.

In these days of flying trips across continents, of globe-trotting excursions to all accessible parts of our little planet, a mere trip from New York to the Riviera should scarcely be made memorable by having thrust upon it the dignity of printer's ink. Nevertheless your correspondent's special mission may be entitled to some consideration from that large class of physicians whose patients annually consult them in regard to the most suitable climate that will afford them a pleasant escape from the rigors of a northern winter. The South of France, the Riviera, Florence, and other Italian cities have for many years been favorite resting-places for those in search of winter sunshine and winter out-door exercise. It is true the health-resorts along the Riviera have been literally written to death. Yet, in spite of this melancholy fact, or, perhaps, rather on account of it, the actual sanitary condition of the most popular Mediterranean stations is almost a terra incognita to the American medical profession. The ordinary guide-book information is certainly incomplete and unreliable, and the testimony of local physicians is apt to be tinged with a pardonable local coloring of decided roseate complexion.

It cannot be denied that many of our best citizens are still anxious to visit the Riviera, are quite eager to see Florence, Rome, Naples, Venice, and other interesting towns. But it must also be admitted that many a sad experience, many an unexpected personal bereavement there has lately created a widespread feeling of distrust in regard to the healthfulness of the places named. Certain it is that for the past two years influenza has spared neither native nor foreigner, neither old nor young in the Riviera, that typhoid fever was virulently epidemic in Florence so recently as last winter, that Roman fever is more than a mere myth, and that Naples and Venice have an uncomfortably high death rate. Under these circumstances many American physicians have very properly preferred to send their patients and convalescents to Florida and Southern California, rather than permit them to hazard an ocean trip, and incur the well-known discomforts of continental travelling, in search of problematical benefits to be derived from a sojourn in Southern Europe. Of course, the trip can now be made from New York by steamer direct to Genoa. But this does not dispose of the main question, viz., the actual present sanitary condition of the resorts still largely frequented by American tourists and invalids.

Under these circumstances, with traditional Record enterprise, a searching tour of inspection is now to be undertaken, and an entirely independent sanitary examination of the most vigorous kind will be made. The results of this inquiry, which is to occupy the entire coming winter, are to be submitted to the medical profession through the columns of the Record.

Ocean journeys are now but slightly dreaded by the public; and there is good ground for this universal confidence. For will not a luxurious floating hotel take you to Southampton, despite all stormy weather, in less than a week? The twin-screw steamers of to-day are truly named ocean greyhounds. Your correspondent, for example, left New York on the Fürst Bismarck on Thursday, November 5th, and on the following Thursday he enjoyed a very comfortable dinner at the Savoy, in London. To still further reduce the time of an Atlantic crossing seems hardly called for, if Father Chronos is not to be for evermore relegated to innocuous desuetude.

London is still the great metropolis of the world, and unless Chicago will embrace in its octopusean tentacles an additional prairie or two the New World will have to wait a little longer before a city containing a five million population will justify such ponderous and pleonastic directories as they bewilder you with in the capital of the land of fogs.

Having been brought up to entertain dreadful suspicions of British "aloofishness," your correspondent, like numerous Americans before him, was agreeably surprised at the cordial reception extended him everywhere in London.

Mr. Ernest Hart, the accomplished editor of the *British Medical Journal*, whose facile pen has, among other things, indited many an entertaining and instructive narrative of professional travel, was most courteous and painstaking in his endeavors to facilitate the work of your correspondent. It is through Mr. Hart's personal letters that your correspondent was able to communicate with Sir Douglas Galton, the eminent sanitary expert, and with Sir Edward Watkin, who has a most intimate knowledge of recent sanitary improvements in the health resorts along the Riviera.

Sir Morell Mackenzie also greeted your representative most cordially, and in a pleasant chat gave him valuable information concerning Riviera matters. Sir Morell's mantelshelf was a sight not before seen in any physician's office, at least by my republican eyes, for it held photographs with autograph dedicatory remarks of almost the entire royal family of England. There were also interesting autograph letters from the Queen to her "Theurer Fritz," written in very good German, and saying nice things about "Vicky." Sir Morell, like other eminent London physicians, has three door-bells: 1, For visitors; 2, for patients; 3, for servants. I am not sure that the Hibernian despots presiding over our domestic arrangements in New York would permit the introduction of such an innovation. And then, again, perhaps it would hardly be necessary, as so few of our medical houses are English basements and so many of our visitors are only patients. But three big bells on your door-front certainly seems rather awe-inspiring. I prefer them to our night-bell and speaking-tube inconveniences. Those speaking-tubes are really quite useless, except in so far as they extend a permanent invitation to practical jokers to rouse us from our deepest slumbers and shout up hasty summonses to illusory patients. As prolific breeders of strong

language in the dead of night, speaking-tubes have no equal among American medical institutions.

The run from smoky London to fashionable Brighton is accomplished in less than one hour and a half, by special train of vestibuled Pullman cars. A homelike sensation of ease and comfort steals over you on board these cars. It is to be hoped that British conservatism, which at present still maintains such antiquated travelling methods, will soon give way to the rational American system of running trains properly heated, properly ventilated, properly lighted, and properly provided with other essential conveniences. The British and continental systems are, with the exception of a few "trains de luxe," barbarous in the extreme and positively dangerous in the case of feeble invalids.

Brighton, the "Queen of Watering Places," is well worth a visit during the height of the season. This lasts from about the middle of October until New Year's. There is certainly a balmy, invigorating quality to the air there that may largely account for its great popularity with "all London." Brighton is clean, decent, and healthful, but it ought to be at its best in the summer months, at the very time when all London fights shy of its charms. I saw only one really fine old building in the place, and that was, according to my communicative cabby, the "'ome for horphans and 'alf horphans." I am glad the poor little ones are so pleasantly domiciled. They deserve it, if everybody calls them such dreadful names. A few fashionable physicians are said to earn as much as $30,000 per annum, but a great many unfashionable ones are believed to earn less than their living expenses at Brighton.

From Brighton back to London, and thence, via Dover and Calais, by fast, cold, dreary train to Paris, is an affair of only eleven hours, including time wasted in a most perfunctory kind of non-McKinley baggage examination. In Paris I found Mr. Blaine's letter of endorsement of my mission, addressed to all the Diplomatic and Consular Officers of the United States, and cordially bespeaking for your correspondent such official courtesies as they may properly extend during his sojourn abroad. Department letters of this character are apt to oil the wheels of official action, which have been known to run in a slow and jerky fashion when left to their own devices.

Shortly after my arrival in Paris I had a conference with Mr. Whitelaw Reid, and, after formally presenting my credentials, requested him to ask, in his official capacity, permission from the French Government to practise my profession this winter in the French Riviera among my own countrymen. In case of failure on the part of the Government to grant this permission (which, according to Mr. Reid's previous experience, was a foregone conclusion) I further inquired what privileges or exemptions could be granted in the matter of passing the regular French State examinations prescribed by the new Law. By going through the mill, the RECORD representative may, perhaps, render the profession at home a service. A test case might possibly be useful in obtaining reciprocal legislation for Frenchmen desiring to temporarily practise in the United States.

The American colony of Paris must be more French than American by this time, if one may judge from the difficulties encountered by some of our physicians in obtaining lucrative practices. The Nestor of American medicine here is the ever-genial, highly-polished, and courteous Dr. Warren-Bey. Paris is not, apparently, a very promising field for American newcomers, and any malcontents had better malcontent themselves by remaining at home, than by seeking fresh fields and pastures new in Paris. However, Dr. Warren and several other well-informed American physicians assured me that the French were most tolerant and quite liberal in the interpretation of their new Medical Law, so long as an American did not intend to permanently reside in Paris. Dr. Prendergast, the late Lord Lytton's physician, and surgeon to the British Embassy, gave me precisely the same information with regard to Englishmen wishing to practice in France. True, the letter of the law does not really permit it, but the law winks here, as elsewhere, when winking seems called for.

In amusing contrast with these straightforward statements, I ought to mention the information vouchsafed me by a recent lofty graduate of some French school. This American gentleman, who was formerly at a well-known military academy in the United States, intimated that he really controlled medical legislation in Paris, and asserted that it was extremely difficult, if not impossible, for an American citizen to obtain any kind of recognition from France. Moreover, he himself would take pleasure in lending his potent aid to still further increase these difficulties. He told various other diverting tales to even more forcibly illustrate the well-bred and obliging nature of his disposition toward his own countrymen. The youthful aspirant for fame is always the same, and he is always amusing, whether you meet him in Paris or in New York, in Oshkosh or in Timbuctoo. From the editor of the Paris *Medical Journal*, who, by the way, speaks English as well as an American, I learned that the RECORD is held in high esteem by English-speaking French physicians.

Our poly-pharmaceutical countryman, Dr. Brown-Séquard, had already gone southward, so that I failed to meet him. I was naturally anxious to see his elixir and, if necessary, even to raise it one. To-day I saw "by appointment" the great Charcot, with whom mere patients are at times permitted to have "audiences." I am afraid there is an "open sesame" attached to RECORD credentials that may easily lead to magocephalism of a dangerous kind. At any rate, Dr. Charcot received me most cordially, wrote me letters to the Dean of the Faculty and other important persons, entertained me for a long time on interesting politico-medical topics, to which I may have occasion to refer later on, spoke about the contrast between the profession of to-day and of times gone by, and with true French *politesse* offered his services in any way in which I should see fit to command them. And all this while his magnificently appointed waiting-room was crowded with patients, anxiously waiting their turn to consult the great French savant.

My next will be my first Riviera instalment, and will be much more impersonal than it was possible to make the present introductory note.

ANOTHER CASE OF LONG-RETAINED PLACENTA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Reading the report of Dr. Lamadrid's case of retained placenta, in the MEDICAL RECORD of November 7, 1891, brings to my mind one of interest occurring in the practice of Dr. Groat, in Fremont, O., in 1864, and I think never reported except before the local society. In this case the placenta was retained fifty-one days, so far as I know, the longest period on record. The patient was a robust Scotch woman, mother of four children, seven months advanced in pregnancy. Excessive physical exercise, together with great fright in time of a sudden flood, caused the death of the fœtus. This was suspected from complete cessation of motion, which had before been very constant.

With too little warning to summon medical assistance, a well developed child of seven months was delivered. The placenta not following after waiting several hours, Dr. Groat was called. He found the uterus contracted upon the placenta quite firmly; the cord short and friable, breaking off near the os.

Ordinary methods to secure expulsion proving unavailing, the doctor concluded not to use force, but await further development, observing the patient closely meanwhile.

Convalescence progressed favorably, the patient was

allowed to leave her bed, then her room, and finally to pursue her usual duties. During the night of the fifty-first day she was awakened with a sensation of straining, and obeying the desire, the placenta was expelled without pain or hemorrhage. It seemed to be entirely natural except that it showed the contracted form of the uterus. After a few days of rest in bed she again attended to her ordinary employment.

FANNIE A. GROAT, M.D.

511 SOUTH NINTH STREET, ST. JOSEPH, MO.,
November 23, 1891.

THE MEDICAL PRACTICE LAW IN MINNESOTA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I noticed recently in your columns comments upon the medical legislation of Connecticut, and I wish to call your attention to the medical laws of one, at least, of our States in the wild West which bears a marked contrast.

Wishing to appear before the State Board of Minnesota for examination, I wrote to the Secretary for particular information, stating that I had degrees from Rush Medical College, '89, and from the College of Physicians and Surgeons of New York, '91, and that I could show evidence of a hospital experience during the time intervening. I received the enclosed reply:

"DEAR DOCTOR: Yours of the 4th received. The Minnesota law requires *three* courses of *at least* six months each. This allows us no discretion. It is impossible for us to recognize any other. Diplomas are not recognized, and, under our law, you are not eligible for examination. I enclose a copy of the law for your information.

"Yours truly,

"ARTHUR SWEENEY, M.D.

"STATE BOARD OF MEDICAL EXAMINERS,
"SECRETARY'S OFFICE, ST. PAUL, MINN., July 17, 1891."

During a personal interview soon afterward with the Secretary of above Board I was told that because the terms of one of the colleges lacked a few days of the required time, I could not appear for examination, and my only recourse was to take two more terms at some reputable college of at least six months each. In this State diplomas from two of the leading colleges of the country will not render one eligible to appear before the State Board of Examiners for examination. The headquarters of this Board is St. Paul. Comments are unnecessary.

Very respectfully,

CARL M. BEEBE, M.D.

LA CROSSE, WIS., November 19, 1891.

TREATMENT OF A BAD COLD.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have just read in the MEDICAL RECORD of November 28th the excellent article on this subject by John Aulde, M.D. The use of gelsemium in bad colds and la grippe cannot be too highly praised. In my own practice I have used it, under certain conditions, for twenty-five years, and during that time I have found it nearly a specific in bad colds and influenza. Two years ago, when la grippe visited this city and nearly "filled our graveyards," myself and others who prescribed this remedy did not lose a single case. During the months of February and March, 1889, I had daily under treatment seventy-five cases, and very bad ones the most of them were. When called early in the attack, gelsemium, without a single exception, averted pneumonia, pleuro-pneumonia, and pleurisy. A leading pharmacist said to me one day, in a jocular manner, "In la grippe gelsemium is death to the undertaker's business, while quinine is death to the patients." Of the seventy-five cases per day three patients had, before my seeing them, contracted pneumonia; I continued the remedy and they too recovered. Ten drops in four ounces of water, a teaspoonful to be given every hour during the day, was my line of practice. I never use the ordinary fluid extract. I have no faith in anything but the tincture made from the green root.

LANCELOT YOUNGHUSBAND, M.D.

DETROIT, MICH.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have just finished reading the able article, under date of November 28th, on "The Treatment of a Bad Cold." I have found that most severe colds may be broken at the outset by a free use of hot ginger tea, taken just before retiring. One heaping teaspoonful of ginger steeped in one pint of boiling water, a large glass of the clear tea poured off, and sweetened, has proved itself to be an efficacious as well as a simple remedy.

MEDICUS.

NEW YORK, December 2, 1891.

OKLAHOMA HAS BEGUN WELL.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: We would like to have it understood that Oklahoma is not a rendezvous for quacks and non-graduates in medicine to flourish in. War is being made on such all over the Territory. Five indictments have been made by the Grand Jury in this county this week, and one travelling charlatan is now lying in jail in this city, not having money enough to pay his fine.

Our medical law requires that a physician shall have a diploma from a reputable medical college, or shall pass a satisfactory examination before the Territorial Board of Medical Examiners.

Very respectfully yours,

J. A. OVERSTREET, M.D.,
Territorial Superintendent of Public Health.

KINGFISHER, OKLA. TER., November 23, 1891.

THE PHYSIOLOGICAL RELATION OF ALCOHOL TO FOOD.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I read with much interest the article in the MEDICAL RECORD, of October 17th, entitled "The Physiological Relation of Alcohol to Food, etc.," and I have been waiting to see some reply as criticism upon it, either as an editorial or as a contributed article. As no such reply has appeared, I venture to raise the question whether a doctrine so revolutionary in its practical bearings is to be accepted without controversy, or to be quietly ignored.

The author speaks as one with authority, and not as the scribes. For example, he teaches that an infant should be "fed according to the laws of nature, and not by the rules of the say sos," but gives no authority but his own "say so," for what he claims the laws of nature require. He does not in any way vindicate the authority of the tables upon which many of his arguments are based, or explain how they were prepared. One of them, Table VII., is at least remarkable. According to it, a person engaged in active labor requires thirty-five per cent. more of albuminous than of carbonaceous food. I would like to see a bill of fare prepared by the author for a laboring man's breakfast, dinner, and supper that would secure such a proportion of the two classes of food. He also teaches that the imperfect oxidation of albuminoids, to which certain diseases are due, is the result of too large a proportion of hydrocarbons in the food, which is diametrically opposed to the teaching of Fothergill and other eminent teachers. Is this new doctrine to be at once accepted as correct, or is there yet something to be said in favor of a diet in which the cereals and vegetables constitute their usual proportions, and in favor of withholding meat and most solid foods from babies under a year of age?

GEORGE H. FELTON, M.D.

NEW ORLEANS, LA., November 11, 1891.

A NEW METHOD OF REMOVING A RETAINED PLACENTA.

To the Editor of the Medical Record.

Sir: Time would fail if I were to atempt to tell of the various means, external and internal, that I have seen used in the thirty years of my medical life to remove a retained placenta. I have seen old women of our own race use teas of cobwebs, soot from a chimney, cotton burned on an axe, as well as such external remedies as a rabbit-skin laid over the uterus, and skunk and rattlesnake oil rubbed on the abdomen to induce the longed-for pains. The long towel drawn tightly around the body was known in Southern Illinois and Kentucky by generations who never heard of Credé. The Hindoos in some places give ewe lamb's urine as well as the urine of a virgin, and they also burn dried cow-dung and red pepper, and cause the woman to squat naked over the smoke. The Chinese often use a broth made of a dried placenta, and the Indians of our country use the broth of the skunk and some other animals, as well as skins of these animals laid over the womb.

I was called some time ago to see a young American woman, who lived in a Mexican neighborhood where there were no other Americans. The young man, her husband, said the old women were very kind, and when the after-birth failed to come, one of them asked for a pack of cards, and from these she drew the four aces, having carefully shuffled them. She burned the cards on a clean iron shovel and mixing the ashes with water, urged the young woman to drink it. She thought it was better to yield than to refuse, so swallowed a part of the mixture, managing to spill the most of it. She and her husband, however, kept up their efforts at bearing down and squeezing, and the placenta finally came away, but the old woman firmly believes it was the aces did the business. I asked the old woman what she would have used had it been a girl, and she said the four queens would have been the proper remedy. This was a new idea to me, and I thought the experience might interest the readers of the Medical Record.

H. R. Palmer, M.D.

Trinidad, Col., November 19, 1891.

A MATERNAL IMPRESSION THAT TAKES THE PRIZE.

To the Editor of the Medical Record.

Sir: Occasionally the past twenty years your journal has contained articles relating to maternal impressions. There seems to be times that physicians like to write on a particular subject, reminding one of a Methodist class-meeting, where every one is invited to free his mind.

That children are born with certain marks referable to some occult cause I do not doubt, for one must believe the evidences of his own senses, even if he cannot explain the phenomena from a scientific stand-point.

The particular incident I have in mind now occurred twenty years ago, and I relate it only because of its ludicrous nature. When Mrs. S——, who lived in one of the towns of this State, was about three months pregnant she had occasion to go to the water-closet in her yard. The closet was so situated that anyone who chose could enter. As it happened when she opened the door a man arose from the seat. Mrs. S—— obtained a full view of the man's genital organs and retired.

In course of time her child was born, and on its abdomen was pictured in bold relief the external reproductive organs of a male. That child is a man to-day, and carries the impressions of the organs mentioned indeliby stamped upon his abdomen through some mysterious agency of nature.

E. J. Bergen, M.D.

Washington, N. J.

A Correspondent, significantly we presume, asks the question if there is any case on record of an American woman giving birth to five children at one time?

ANOTHER MATERNAL IMPRESSION.

To the Editor of the Medical Record.

Sir: I contribute my morsel to the symposium on maternal impressions. Mrs. S—— has thirteen children, all perfectly formed except the tenth, who has a congenital cataract in his left eye. When she was one month gone in this pregnancy the late Dr. Agnew removed the left eye of her only grandchild for irido-choroiditis. The removed eye was blind, and showed a gray reflex from the fundus. Naturally the occasion of the operation was one of great excitement and sorrow throughout the entire family, and the grandmother was especially troubled. Eight months after the operation the delivery occurred, with the result above stated. The new-born child showed the same gray reflex from the pupil that had been observed in the grandchild, but from an entirely different cause, viz., congenital cataract.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department. United States Army, from November 29, 1891, to December 5, 1891.

Glennan, James D., First Lieutenant and Assistant Surgeon. Granted leave of absence for one month, with permission to apply for an extension of one month.

Burton, Henry G., Captain and Assistant Surgeon. Ordered to report to the president of the Army Retiring Board at Los Angeles, Cal., for examination by the board; on conclusion of his examination will return to his station at San Diego Barracks, Cal.

Shillock, Paul, First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Yates, N. D., and ordered to Fort Grant, Ariz. Ter., for duty.

Suter, William N., First Lieutenant and Assistant Surgeon. Relieved from further duty at Fort Grant, Ariz. Ter., and assigned to duty at Fort Bowie, Ariz. Ter.

Taylor, Arthur W., Captain and Assistant Surgeon. Having been found incapacitated for active service by an Army Retiring Board, will proceed to his home.

Stephenson, William O., Captain and Assistant Surgeon. Relieved from duty at Columbus Barracks, O., and will report in person to the commanding officer at Fort Niagara, N. Y., for duty at that post.

Official List of Changes in the Medical Corps of the United States Navy for the week ending December 5, 1891.

Heyl, T. C., Surgeon. Placed on the retired list, December 3, 1891.

Jones, W. H., Surgeon. Promoted to Medical Inspector, November 14, 1891.

Anderson, Frank, Passed Assistant Surgeon. Promoted to Surgeon, November 14, 1891.

Blackwood, N. J., Assistant Surgeon. Detached from Navy Yard, League Island, Pa., and ordered to the Miantonomah.

Morris, Lewis. Assistant Surgeon. Ordered to the Navy Yard, League Island, Pa.

A Too Zealous Malthusian.—An Oxford M.A. and legal practitioner has been arrested and fined in London for circulating pamphlets with directions for preventing conception. It was his habit to study the announcements of births in the newspapers, and send one of his circulars to the happy father.

Varicella	5	0
Pertussis	3	1
Erysipelas	1	0
Mumps	0	0
Rötheln	0	0

Hard Chancre of the Lip and Soft Chancre of the Genitals.—Dr. P. I. Messarosh relates, in the *Meditsinskoye Obozrenie*, No. 17, 1891, the case of a young man, twenty years of age, who presented himself at the Astrakhan General Hospital for treatment of a sore lip. Examination revealed the presence of a true Hunterian chancre on the upper lip, and also a soft chancre of the penis. The patient stated that he had accidentally bitten his lip some time before, and that soon thereafter a sore appeared which refused to heal in spite of numerous domestic remedies which he had applied. While the man was still under treatment a woman presented herself for treatment for syphilis. She was found to be suffering from general syphilis, having mucous patches in the mouth, and also from soft chancres in the vagina. This woman, it was subsequently ascertained, was the mistress of the other patient, with whom he had lived for several months, and from whom undoubtedly he had acquired his lesions.

Tuberculin in Russia.—The Russian authorities have forbidden any further experiments with tuberculin in the military hospitals of that country, in consequence of the negative, or even positively injurious, results that have thus far been obtained.

Outstanding Ears.—Mr. William Thomas, of Birmingham, describes, in the *British Medical Journal* for October 17, 1891, the following operation by which he has succeeded in making flaring ears lie close to the head. The operation consists in the removal from the inner surface of the pinna of an elliptical piece of skin, dividing the cartilage of the pinna down the centre of the exposed cartilaginous surface, and uniting the margins of skin by sutures. The widest part of the skin removed should be from half to three-quarters of an inch, but of course this depends on the degree of deformity. It is necessary to divide and turn back the cartilage, not only to remedy the deformity but also to allow of easy approximation of the skin margins, and care must be taken to avoid division of the outer skin with the cartilage. The after-treatment consists in the application of a small cotton-wool pad between the head and the pinna—the latter being fixed by a bandage until healing is complete. Immediately union takes place, and there is hardly any perceptible scar, the skin of the ear having great vitality. A simple method of keeping the outstanding ears back without operation is to fix them by a piece of lint soaked in collodion, and placed between the pinna and the head, the ears being bandaged close to the head until the collodion is firmly set. The adherent splint thus formed will hold the ear in position for two or three weeks, when it may be renewed. It is, however, only a temporary measure. The principles of the operation are applicable to various malformations of the pinna.

CONSERVATIVE SURGERY APPLIED TO THE OVARY.

BY T. GAILLARD THOMAS, M.D.,

NEW YORK.

History of Case.—Mrs. P——, a nullipara, married three years but never pregnant, came on from Cincinnati to consult me about October 1st of the present year, on account of sterility, painful and irregular menstruation, pelvic neuralgia extending down the thighs, depression of spirits, persistent leucorrhœa, and impaired nutrition, which demonstrated itself by emaciation, or rather by the absence of all tendency to adipose deposits.

Upon physical examination the uterus was found decidedly anteflexed, and the cervical mucous membrane granular from prolonged contact with ichorous leucorrhœal discharge. The left ovary was found to be as large as a small hen's egg, prolapsed and tender; and the right ovary as large as a small orange, or a large goose egg, prolapsed low down in the pelvis a little below the brim, and firmly fixed by adhesions.

The patient entered my hospital about October 15th, and laparotomy was performed at 10 A.M., on October 28th.

Description of Diseased Parts.—Upon opening the abdomen, the left ovary was found to be unattached by adhesions. It was as large as a small hen's egg, had a number of little peripheral cysts over its surface, and upon palpation presented unmistakable evidences of containing fluid of dense character. This ovary, with its corresponding Fallopian tube, was removed in the ordinary way, and upon being bisected, presented the appearance depicted in Fig. 1. The superficial cysts were, apparently, due to dropsies of the Nabothian follicles. The centre of the ovary was occupied by a mass of black, grumous blood, about as solid as that which usually makes up the bloody material of a pelvic hematocele. This was the result either of an ovarian apoplexy, or of a small blood cyst; I am decidedly of the opinion that it had the former origin.

FIG. 1.—Left Ovary with Superficial Cysts in Stroma, and Large Blood-mass in Centre.

The right ovary with a thick-walled cyst, which existed between itself and its ligament below and the Fallopian tube above, was firmly fixed by adhesions in the pelvis, and had to be enucleated, or "shelled out" by tearing attachments with the finger. Lifted into the abdominal opening, the condition of the parts was found to be that shown in Fig. 2.

The tumor depicted was one developed in the right broad ligament, and was firmly attached to the Fallopian tube above, and the surface of the ovary below.

Operation.—The patient was extremely desirous of becoming a mother, and I was very averse to following the usual practice of ligating the parts below the ovary and removing this organ together with the cyst and Fallopian tube. Instead, therefore, of doing this, I split the broad ligament with a bistoury guided by a grooved director, and at the expenditure of considerable time shelled out

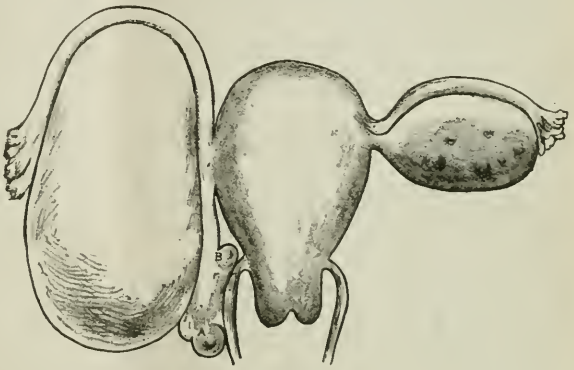

FIG. 2.—Showing Relation of Parts Described in Text. *A* and *B* are Cysts of Right Ovary as Large as Cherry-stones.

the cyst entirely and without evacuating its contents. Then I applied a half dozen ligatures of Chinese silk to the bleeding vessels, and with fine catgut closed the opening in the broad ligament carefully and completely.

Two cysts as large as cherry-stones were found in the ovary. These were opened and their cavities lightly cauterized with Pacquelin's thermo cautery brought to a white heat. Then the Fallopian tube which, in consequence of these manipulations, had been broken completely away from the ovary, was attached to that organ by a strong catgut suture, the parts were returned to their normal places, and the abdominal wound was closed by silkworm gut.

The patient, as soon as ether narcosis had passed off, was made happy and hopeful by the announcement that the prospects of maternity had not been destroyed by the operation, but on the contrary, had been much increased. Upon receiving this intelligence she said, very promptly and decidedly, "Thank you for telling me this at once; now I shall surely get well, for I desire very much to live and am determined to recover. Had you confirmed my fears as to the result of the operation upon the prospects of having children, I should have been indifferent as to the end."

The steps of the operation, simple as they were, were very tedious, and over an hour was expended in their performance. Mrs. P—— made a rapid and easy recovery, and at the next regular menstrual epoch menstruated normally and painlessly, as I very confidently expected that she would do.

Although this case presents no features of great interest or moment, I report it as a contribution to the daily growing subject—the conservative surgery of the ovary. Certain I am that ten, or even five, years ago in my hands the ovary, which in this case has been saved, would have been destroyed; one more sterile female would have been added to the number daily created by the gynecologist; and one more disappointed and sorrowing woman made to swell the already long list of those who bemoan a childless existence.

CLINICAL REMARKS ON ACUTE PULMONARY ŒDEMA.[1]

By A. ALEXANDER SMITH, M.D.,

NEW YORK.

ŒDEMA of the lungs is of such frequent occurrence and presents itself under such a variety of conditions, it seems not amiss to discuss its means of relief. In itself a very serious symptom, it always indicates a grave pathological condition in the organism. While it may occur in the course of a great variety of diseases, the most frequent conditions under which it occurs is in disease of the heart, or the lungs, or of the kidneys.

The transudation of serum into the tissues may depend on many causes—the condition of the blood, the condition of the walls of the blood-vessels, the condition of the heart-power, obstruction to the flow of blood, the amount of urine secreted, and the condition of functional power of the nerve-supply to the blood-vessels and the viscera.

An hydræmia is the recognized condition of the blood as almost essential to the occurrence of œdema in the vast majority of cases. But hydræmia alone will not suffice to explain all cases of œdema. The blood has by experiment been overloaded with a saline solution producing an "artificial hydræmia," and yet rarely has œdema been produced under such circumstances.

Changes in the walls of the blood-vessels by which they become abnormally pervious, favor the transudations. These changes may be due to hydræmia, at least may largely depend on it. To perform their functions properly, the walls of blood vessels must have not only good blood to act upon, but they derive their nutriment from the fluid they carry, and their nerve-supply must be unimpaired.

An enfeebled heart is recognized as a condition favoring the transudation of serum, whether this enfeeblement be due to disease of the heart itself or to disease elsewhere, producing enfeeblement of the heart-wall. The experiments of Welch seem to show that this enfeeblement in pulmonary œdema must be of the left ventricle. But this alone does not seem to satisfactorily explain all cases of pulmonary œdema. How often we see most marked enfeeblement of the left ventricle from various causes and no pulmonary œdema occurs.

Obstruction to the flow of blood from any cause, especially when it allows of venous stasis, favors the escape of serum from the blood-vessel walls. But mere mechanical obstruction will not always satisfactorily explain the occurrence of an acute œdema. The familiar experiment of Ranvier of tying the femoral vein produced no œdema, but when he severed the nerves supplying the vessel œdema appeared quickly. That interference with the proper functional activity of the nerve-supply to the blood-vessel wall plays an important part in the production of œdema I am convinced is the only satisfactory explanation of the occurrence of œdema in some cases. This is especially true of pulmonary œdema. In cirrhotic kidney not infrequently a pulmonary œdema will occur suddenly, and that too when the patient does not suffer from œdema elsewhere, as of the surface and in the large serous cavities. As is well known cardiac hypertrophy is more apt to accompany this form of renal disease than any other. Even with an hypertrophied heart, in some of these cases pulmonary œdema will occur. There is not present any marked condition of hydræmia; the heart is hypertrophied; to be sure, there are apt to be marked changes in the walls of the blood-vessels, especially of the arterial system; yet pulmonary œdema occurs and occurs quite suddenly. The explanation, it seems to me, is in the effects of the poison on the ganglionic system, interfering with its proper function, causing it to lose its control over the walls of the blood-vessels, and a transudation occurs. An additional explanation might be found, too, in its poisonous effects on the respiratory centre. The sudden effect of the accumulated poison on the nerve-centres and on the ganglionic system is forcibly illustrated in so-called uræmic dyspnœa. The difficulty comes on very suddenly and disappears almost as suddenly. The attacks come on most frequently in the evening or at night. Sometimes in such cases the gastric distention occurring after a meal interferes with the free movements of the diaphragm. This interference may be the exciting cause of an attack of dyspnœa, but when the attack comes on during the night, as not infrequently happens, it cannot be explained in this way. There seems to be no satisfactory explanation, except on the ground of the effects of the poison on the nerve-centres and on the ganglionic system. Pulmonary œdema may come on as suddenly, although such occurrence is more rare than in uræmic dyspnœa. An attack of acute pulmonary œdema may be the first grave symptom suggesting kidney disease.

Again, in acute renal disease pulmonary œdema may occur as a complication, and that, too, of a severe character and quite suddenly. This may take place before hydræmia has developed to any great extent and before the disease has existed a sufficient length of time to cause changes in the heart-muscle. Now it seems to me its occurrence under such circumstances must be attributed largely to the influence of the poison on the nervous system, and especially on the ganglionic system. The serum transudes from the walls of the blood-vessels. The vasomotors preside over the functions of the blood-vessels and afford channels of communication between the blood-vessels and the nerve-centres. It seems rational that any agent, such as the poison which accumulates in renal disease, which produces such a deleterious influence on the nervous system, might so interfere with the proper function of the walls of the blood vessels as to allow the serum to transudate.

The quantity of urine secreted is an important factor in many cases, and yet how often we observe cases in which there is a very small quantity of urine secreted and no œdema occurs; at least not until the kidney disease has existed for so long a time that changes have occurred in the blood, in the heart-muscle, and in the walls of the blood-vessels. I have no doubt every member of the New York County Medical Society can recall cases in which cessation of urinary secretion lasted for several days and in which no œdema occurred. I have seen such cases and many have been reported. A patient a few years ago at Bellevue Hospital had one kidney removed and there was no urine secreted for eleven days and no œdema occurred. Of course the skin acted freely all this time.

The autopsy showed that her only kidney had been removed. These statements seem to be almost contradictory. In some persons there seems to be an extraordinary tolerance to the poison which should be eliminated by the kidneys, and in others only very slight tolerance.

The time-honored, traditional, and I might say orthodox treatment by the application of dry cups to the chest-walls is disappointing; at least it can play but a small part in the relief.

Alcoholic stimulants have been unsatisfactory. I am inclined to think they actually do harm by increasing the difficulty. The left ventricle is trying to force the blood into an arterial system already obstructed because of the stasis in the venous system.

[1] Read before the New York County Medical Society, November 23, 1891.

The method of treatment I have found most successful in many cases is a combination of strychnine and atropine by hypodermic injection and nitro-glycerine by the mouth. The quantity used is $\frac{1}{30}$th grain strychnine and $\frac{1}{100}$th grain atropine, given together, and $\frac{1}{100}$th grain nitro-glycerine at the same time. The conditions which have resulted in a pulmonary œdema have also lessened the power of the stomach to take up medicinal agents; at least we cannot be so certain of their absorption as when given hypodermically. The nitro-glycerine is so diffusible it is very readily absorbed and produces its effects very quickly, as much so when swallowed as when given under the skin. Usually these are repeated in two hours. The strychnine increases the force of the heart by stimulation of the heart-muscle and its ganglia, while there is also stimulation of the vaso-motor centre. It is the most constant and powerful respiratory stimulant we possess. The atropine increases the force of the heart and stimulates the vaso-motor and respiratory centres. The nitro-glycerine dilates the arterial blood-vessel system, probably by its action on the vaso-motors, thus relieving the venous stasis. It acts to distribute the blood throughout the arterial system, in this way relieving an over-worked and weakened heart. By its action on the arterial system it gives the strychnine and atropine a better opportunity to produce their physiological effects more decidedly, it by rapid diffusion throughout the system, they by acting on the heart and respiratory centre, enabling the heart to do its work more freely and forcibly. After the first repetition the atropine is discontinued and the nitro-glycerine and strychnine continued every two hours until relief is marked.

Opium and nitro-glycerine have given the best results in pulmonary œdema occurring as a complication of acute renal disease, and in cases of sudden pulmonary œdema in renal disease accompanied by hypertrophied heart. The sudden accumulation of poison acts on the nerve-centres and on the vaso-motors, interfering with their regulation of blood in the capillaries. The opium counteracts the effects of this poison, and the nitro-glycerine aids in the restoration of the functions of the capillaries. In acute so-called uræmic poison it is not at all uncommon, when the convulsions have been controlled and the coma relieved by opium, to find the kidneys resuming their functions. It seems to me that the explanation of this is not at all difficult. The nerve-supply to the kidney has been acted on by the accumulated poison in such a way as to destroy its function temporarily. The opium neutralizes the effects of this poison on these nerves, rests them, as it were, and they resume their function. Besides the effects of this accumulated poison on the blood and blood-vessel wall, there is an effect produced on the nerve-supply to such blood-vessels, those in the lungs, as well as those in the brain. The opium neutralizes this effect and the function of the nerve-supply to the capillaries is restored. The dose I have usually given is $\frac{1}{6}$th grain morphine and $\frac{1}{100}$th grain nitro-glycerine every two hours until relief is obtained. When cyanosis with pulmonary œdema is very marked, oxygen has seemed to me to give relief to the dyspnœa, if cautiously administered. I have had more satisfactory results by giving it with the tube, not too near the patient's mouth, say two inches from it, mixing it in this way with atmospheric air. I have seen the difficulty of breathing much aggravated if pure oxygen is administered too freely. In fact, a patient with acute pulmonary œdema will usually refuse to take the tube in his mouth, because of its obstructing his efforts at breathing.

Quickly acting cathartics will aid in the relief, but we cannot rely entirely on them, as we cannot wait for them to act. They can be given in connection with the other treatment suggested. I have found the salines give the best results.

In the acute general pulmonary œdema occurring in connection with pneumonia, the strychnine and atropine and nitro glycerine have given relief often. Of course if this pulmonary œdema is due to the general failure of vital powers just preceding death, as occurs in this as in many other diseases, neither this nor any other treatment will be of avail.

THE TREATMENT OF UTERINE HEMORRHAGE.

By HERMAN E. HAYD, M.D., M.R.C.S.Eng.,
BUFFALO, N. Y.

In the treatment of hemorrhage we must endeavor, as far as possible, to find the cause, in order to bring about such a condition of the body as will lessen any tendency to blood stasis. In a general way we may say, the more the bleeding is due to local causes the more likely will it be controlled by local measures. If anæmia, with its consequent loss of tone and a generally relaxed condition of the system, be the principal causative feature, tonics in the shape of iron—especially the tincture of the chloride—arsenic, and an abundance of good nourishing food, and outdoor exercise, and brisk dry rubbing, or even a daily cold sponge-bath, if borne, will be indicated. Occasionally plethora may be responsible, and if so, it is best met by brisk saline cathartics, a simple but nutritious diet, and active exercise, especially walking, and regular systematic gymnastics. If obstructive causes in remote organs be present, as valvular heart lesions, lung, kidney, or liver complications, etc., such general measures should be employed as would naturally be suggested. However, uterine hemorrhage, either as menorrhagia or metrorrhagia is more often the result of local disease in the uterus or its appendages, and will be satisfactorily controlled by relieving or curing the diseased conditions which produce it.

In recent subinvolution following abortion, where slight hemorrhage continues for days and even weeks, due to a want of tonic contractility in the uterine muscle fibre, vaginal faradization every day, or every other day, will be found eminently satisfactory. The use of ergot, even in large doses, alone or combined with other uterine stimulants, is often not sufficient to control this condition, and there soon results from a simple inertia a possible chronic subinvolution with fungous endometritis, salpingitis, and all their attending complications. Moreover, after too frequent child-bearing, or in conditions of debility accompanying recent parturition, when the womb lacks its proper contractile power, and as a result absorption and involution are impeded, the faradic current combined with general tonic treatment will give the most gratifying results.

Mrs. F——, aged thirty-four; second confinement; first, nine years ago. Labor satisfactory and no special hemorrhage. Physical condition much below par; extremely debilitated, thin and emaciated from the exhausting vomiting, which persisted during the greater part of utero gestation. Slight bleeding persisted for three weeks, notwithstanding rest in bed during the whole period, regular and systematic applications of the child to the breast, injections of very hot water, and the administration of ergot, and good, easily digested food. Vaginal faradism was employed, with the effect of at once stopping the hemorrhage, increasing the tone of the vagina and uterus, and bringing about constant and continuous contractions, which resulted in a satisfactory involution. The patient was permitted to get up, and by the end of the fourth week could walk with comfort. The womb was in good position, of course heavy and enlarged, and there existed but very little leucorrhœa. The applications were continued for one month, and were made by the patient herself every day, the *séance* lasting about seven minutes, the strength of the current estimated by her own feelings, and as much was taken as could be conveniently borne. The bowels became regular, the appetite improved. The general condition was satisfactory, and the woman made an excellent recovery.

Mrs. T——, abortion at third month, a well-nourished woman of good fibre, complained of hemorrhage and pain in the lower abdominal regions. This bleeding had continued for three weeks, notwithstanding the administration of ergot and other remedies. I satisfied myself that no piece of placenta, or secundines remained in the uterus, and that the hemorrhage was probably due to a want of tonic contractility of the uterine muscle-fibre, the result, perhaps, of too early exercise, the patient having gotten up on the third day. Vaginal faradism was then employed, with the effect of completely and permanently stopping the hemorrhage. The treatment was continued for a few weeks, in fact until the second period came on, which was normal in amount, and without pain. The result of the treatment in these two cases suggests the employment of the faradic current in all recent uncomplicated cases of subinvolution, and shows conclusively how chronic womb troubles, with all their accompanying distress and dangers, can often be avoided, and without adding any element of danger by needless intra-uterine medication.

When the subinvolution is of long standing other pathological conditions become important factors in the case, namely, enlargement from hyperplasia of tissues, with accompanying malpositions, chronic catarrhal processes, either as endometritis or endocervicitis, salpingitis, and often ovaritis, para- and peri metritic deposits. In all of these conditions properly directed electrical treatment will greatly assist other recognized measures in bringing about a more speedy, as well as satisfactory cure. In these conditions more than a muscle tonic is required; consequently, galvanism with its chemical and electrolytic properties is indicated. There is no doubt that much trouble has resulted from the careless and indiscriminate use of the intra-uterine electrode. Just as the passage and use of the uterine sound is attended with certain dangers, so will the introduction of the uterine electrode into the uterine cavity, if no regard is shown for the surrounding tissues. The golden rule to have constantly in one's mind in intra-uterine medication is to lessen all active inflammation in the tubes and ovaries by positive vaginal galvanism or by the fine faradic coil—as recommended by me in the *Archives of Gynecology, Obstetrics, and Pædiatrics*—which is more sedative, analgèsic, and anti-inflammatory in its effects. By reducing all active perimetritic inflammation to such a degree that an examination produces but little or no pain, which is usually accomplished even in severe cases in from six to ten treatments, using no force in the placing of the electrode and keeping it as quiet as possible when in the cavity, using low currents, having short sittings in the first applications, and by exercising due antiseptic precautions, there is practically no danger in the use of electricity, and only good and satisfactory results will crown our efforts in most cases.

When one is satisfied that there exists much degeneration of the endometrium, which can fairly well be demonstrated by the profuse uterine discharge, persistent and active hemorrhage (especially when the sound is introduced), curettement is indicated. In order to prevent the return of these granulations, positive galvanism, from fifty to sixty milliampères, a few days after the operation, and continued twice a week for a few weeks, will ensure us against their return. I believe that positive galvanism will destroy this condition, even without a previous curettement; but if time is an element in the case a cure will be more readily brought about by first scraping the uterine cavity, and then applying the current. Malpositions, consisting of a moderate degree of prolapse, anterior or posterior displacements, when consequent upon a heavy subinvoluted organ, are unquestionably relieved and often cured by the same means which is being employed in the treatment of the hemorrhage. Electrolytic decomposition and absorption of lymphoid elements takes place, a large, swollen, displaced womb becomes smaller and in its involution has a tendency to assume a normal position. When the malposition has existed for a long time and a decided atrophy of tissue has taken place at the seat of curvature, or adhesions hold the body in its altered position, other means must suggest themselves. Occasionally a pessary may be of service, but I am inclined to believe that in most cases these awkward appliances do more harm than good, by exercising continuous distention upon the vaginal walls, and at the best setting up more or less irritation by their presence. Well-applied tampons and the faradic current, I believe, will do much more in these cases and serve their purpose upon physiological principles. Add to this regular and systematic massage and uterine manipulation as suggested by Brandt, and I am satisfied few cases will require any other measures.

When the hemorrhage is the result of enlargement of the womb, as well as engorgement of its mucosa, consequent upon extreme laceration of the cervix and eversion of its lips with cauliflower excrescence, the edges of the torn cervix should be denuded and brought together, and the womb thoroughly curetted. But if the laceration is not deep, and the eversion which exists is more the result of chronic inflammatory changes in the cervix, resolution will be accomplished without operation, and a satisfactory recovery in most cases result from properly directed local treatment, and here I can particularly mention galvanism—the positive pole, fifty to sixty milliampères twice a week, so long as there exists any tendency to hemorrhage, and then substitute for it negative galvanism. I employ glycerine tampons to hold the uterus in place and to encourage the profuse watery discharge, and vaginal faradism to tone up the relaxed condition of the vagina and uterine ligaments, which are usual conditions in these cases.

Mrs. L——, aged thirty-one. Miscarriage eight months ago; ovum five months. She had subinvolution and anteversion of the uterus. There was a small polyp on the anterior lip of the cervix, which was, however, removed with the forceps. There was double laceration of the cervix with some eversion of the lips, the os was much enlarged, and deeply congested, and here and there were denuded spots. The patient had endocervicitis and endometritis with thickening of both ligaments, and the vaginal vault was contracted. The womb was bound down anteriorly from peri-metritic adhesions, and a painful, exquisitely tender swelling existed in the left broad ligament, probably an inflamed ovary. The sound entered four inches. The menstrual periods come every three weeks, and there is much pain before and during the first day. She loses much clotted blood, and the flow lasts seven or eight days. The patient is much reduced in flesh, is pale and anæmic, and complains of weakness and fatigue, especially upon exertion. She has pain in the back and sides, especially on the left, extending into the leg; bearing-down pains and distress in the bladder.

A fine faradic coil of the Gaiffè battery was used, with the Apostoli large-sized double vaginal electrode. First one cell was connected, then the primary coil was withdrawn from the secondary, and two cells attached, and so on until six cells were connected, and a powerful current was generated. The *séance* lasted fifteen minutes, with the effect of lessening very materially the pain and tenderness, enabling me to make a very vigorous and thorough examination. This treatment was repeated every other day for two weeks. Hot-water injections were employed, and the vagina was thoroughly packed with glycerine and iodoform tampons. After six faradic treatments the pain and tenderness upon examination were so slight that the faradic current was discontinued and positive galvanism was employed, first of the strength of thirty, but gradually increased to sixty milliampères. The electrode was moved from place to place over the vaginal vault.

Thirteen treatments were made. There was material diminution in the swelling about the tubes, the thicken-

ing and infiltration were much less, and the womb was quite movable. It was now deemed advisable, as well as prudent, to insert an intra-uterine electrode, and apply positive galvanism, thirty milliampères to the lining membrane of the uterus. No pain or great discomfort accompanied or followed the treatment, and at the next visit fifty milliampères were administered. These applications were continued for two months, and at the end of this time the patient was discharged cured. The last note in my case-book was: "Period came with little or no pain; used seven napkins; sick four days. Has no pain in her marital relations. General physical condition excellent, and gained seventeen pounds in weight."

Hemorrhage resulting from a fibroid tumor can usually be controlled by positive galvanism; at all events, the results have been so encouraging in my hands that I shall always first employ this treatment before resorting to other operative measures. Occasionally the faradic current is very useful in assisting the expulsion of a uterine polyp, so that an écraseur can be applied, and complete its delivery, as happened in one case under my care when profuse and exhausting hemorrhages had existed for months.

SUBGLOTTIC LARYNGITIS, OR CATARRHAL CROUP, AS ONE OF THE MANIFESTATIONS OF LYMPHATISM.

By F. H. BOSWORTH, M.D.,

Professor of Diseases of the Throat in Bellevue Hospital Medical College, New York City.

In a recent article on the subject of "Lymphatism," read before the American Climatological Society, September 23, 1891, I took the ground that, underlying the development of hypertrophic changes in the faucial and pharyngeal tonsils, was a systemic dyscrasia, of the existence of which the presence of these hypertrophies should be accepted as evidence. This dyscrasia exerts its influence on the lymphatic tissue, and is therefore designated as lymphatism.

A number of cases which have come under my observation recently, have induced me to somewhat extend this domain of lymphatic influence, and suggest that probably a large majority, if not all, cases of what are usually designated as subglottic laryngitis are really the result of hypertrophic changes in the lymphatic structure situated in the mucous membrane of the subglottic portion of the larynx.

The following cases are selected as presenting points of special clinical interest, two of them in children and two in young adult life.

Case I.—On May 6, 1891, I was called to see, in consultation, a child aged six months, suffering from laryngeal dyspnœa. The disease had existed for thirty-six hours, and was apparently the result of a cold. The child was a strong, healthy baby, who about six weeks before had had a mild attack of croup, which had passed away. The present attack was ushered in with hoarseness, slight cough, followed by complete aphonia and dyspnœa at the end of about six to eight hours. The breathing was stridulous and the dyspnœa both inspiratory and expiratory, and was somewhat paroxysmal in character, the dyspnœic attacks coming on, lasting from one to three hours, and then subsiding. During the intervals the breathing was slightly stridulous, but not especially labored. When I saw the child the dyspnœic symptoms were marked and somewhat distressing in character. The temperature was 99⅘° F., the pulse rapid and strong, and the skin moist. The difficulty in breathing was of such a distressing character that tracheotomy seemed to be urgently demanded; and yet, failing to find any evidences of pseudo-membranous formation, I concluded that we had to deal here with a subglottic laryngitis. Furthermore, the faucial tonsils showed such evidences of hypertrophic changes that I felt warranted in the conclusion that the disease was of lymphatic origin. The child was placed immediately upon the syrup of the iodide of iron, five-drop doses being administered every hour. The dyspnœa continued for about four hours after the first dose of the medicine, during which time, fearing that medication had failed to give relief, preparations were made for the performance of intubation. The symptoms however began to abate, and operative interference became unnecessary. The child was subsequently placed under a course of treatment with the iodide of iron, and up to the present date there has been no return of the croupy attack.

Case II.—On November 9, 1891, a child, four and a half years of age, was brought to me for treatment. She was a slender, delicate child, who had been especially liable to attacks of sore throat for some two years back; these were usually attended with attacks of croup, which were often of a somewhat alarming character, usually occurring at night. I found the faucial tonsils notably enlarged, although the pharyngeal vault was clear. The faucial glands were both removed at a single sitting by means of the guillotine. On the same night the child was seized with one of her croupy attacks, which was mild in character and passed away. On the second night another attack came on somewhat suddenly, and of a rather severe type. An examination of the larynx at this time showed a well-developed subglottic laryngitis, the mucous membrane immediately below the vocal cords being notably swollen and protruding itself well into view below the free edge of the vocal bands. The child was immediately placed on fifteen-drop doses of the syrup of the iodide of iron every hour, for four or five doses, and the next day, the acute attack having disappeared, she was put on a somewhat protracted course of the same drug. There has been no return of her croupy attacks.

The following cases occurred in young adult life, and at a period when a subglottic engorgement gives rise to a vocal impairment and cough rather than to dyspnœic symptoms.

Case III.—This was the case of a young lady, aged thirteen, who consulted me in the fall of 1884. She was especially liable to colds, which developed in the form of a most curious coarse, harsh, barking cough, which was paroxysmal in character and very persistent. These attacks would last from two to four days, during which the paroxysms of barking cough would come on at intervals of every four or five minutes. She had hypertrophic rhinitis, deflected septum, with enlarged faucial and pharyngeal tonsils. The larynx showed notable subglottic thickening, the bulging mucous membrane being clearly seen in outline projecting beyond the vocal band when abducted. This condition I regarded as purely catarrhal in character, as regards the subglottic larynx, and hence depended for treatment mainly on the relief of the intranasal disorders. This patient was under occasional observation for two or three years, during which time the catarrhal disorder was relieved. These curious attacks of barking cough, however, still continued, although with diminished frequency. I finally made up my mind that there was a lymphatic element in the subglottic disease, and removed the faucial, pharyngeal, and lingual tonsils. The removal of the faucial and pharyngeal tonsils did not seem greatly to modify the attacks; the removal of the lingual tonsil, however, was followed by almost complete arrest of her peculiar attacks of barking cough. This patient was subsequently placed under a course of treatment with the iodide of iron. The interesting feature of the case was the disappearance of her attacks by the excision of the lingual tonsil, before she was placed under the course of the iodide of iron treatment.

Case IV.—This was the case of a young lady, aged twenty-five, who consulted me October 31, 1890, in regard to a moderate amount of catarrhal trouble, which she had suffered from since an attack of diphtheria at the age of eight. Her catarrhal trouble was not the source of much annoyance, but she had a fine soprano voice, and she found the notes of the head register im-

paired, the voice tiring easily with the effort at taking the high notes, although the tone seemed to be fairly clear. An examination showed a characteristic thickening below the cords of a subglottic laryngitis, although the vocal bands themselves were perfectly normal. The nasal passages were in a fairly healthy condition, the pharyngeal vault showed evidences of naso-pharyngeal catarrh, while at the base of the tongue there was found a large lingual tonsil in which the crest of the epiglottis buried itself, especially in the enunciation of the high notes. The subglottic affection in this case did not seem to give rise to any prominent symptoms with reference to the larynx, and yet the swelling in this region was quite as marked as in any case which I have observed in adult life. The lingual tonsil was successfully extirpated at a single sitting, being taken out in a number of pieces by means of the snare. On examination a week later, the parts had thoroughly healed up, and the patient reported an almost complete restoration of vocal power. An examination of the larynx showed, very much to my surprise at the time, almost a complete disappearance of the subglottic swelling.

The feature of especial interest in these two latter cases is, that the subglottic swelling subsided so promptly after the removal of the hypertrophied lymphatic tissue at the base of the tongue. Why this should occur, it is perhaps not easy to give an explanation; the clinical feature, however, seemed to my mind clearly established. Furthermore, this seemed to indicate such a direct relation between the two conditions as to suggest to my mind that the subglottic disease was also lymphatic in character; a view which subsequent observation, especially with reference to young children, seemed to confirm.

A subglottic laryngitis has usually been regarded as purely of a catarrhal nature, and the thickening to be due to either a turgescence of the blood-vessels or hyperplasia of the mucosa proper. If we consider these cases carefully, however, it seems difficult to understand how such a notable hyperplasia should occur in this region; certainly it is difficult to understand how a catarrhal inflammation should confine itself to the subglottic larynx without involving the supra-glottic portion with the vocal cords.

In both the third and fourth cases related above, the vocal cords and supra-glottic larynx were practically healthy, and yet catarrhal inflammation of the upper air-tract almost invariably extends, by continuity of tissue, as involving the larynx, trachea, and bronchi. We are forced to the conclusion that the morbid process in subglottic laryngitis cannot be of a purely catarrhal character. The lymphatic tissues are especially developed in the neighborhood of the faucial arch, being met with here in large masses, constituting the faucial, pharyngeal, and lingual tonsils. Furthermore, as we know, they are especially liable to become the seat of hypertrophic changes in child life. Sappey [1] has shown us that in adult life the lymphatic distribution greatly diminishes as we pass downward from the faucial region, and is notably impoverished as we pass into the subglottic larynx. During adolescent life, however, this gradual diminution does not present in such a marked degree, and the subglottic larynx is the seat of a comparatively rich lymphatic distribution. It is this tissue, then, I am disposed to think, that bears the brunt of the diseased action in subglottic laryngitis, in the large majority, if not all cases, and not the mucous membrane proper. If this view be the correct one, the teaching of the cases which I have reported above seems quite clear, and the treatment of a child subject to attacks of subglottic laryngitis or catarrhal croup is removed from the domain of doubtful topical applications, counter-irritants, emetics, expectorants, and such remedies. In place of these we substitute the internal administration of iodide of iron, a remedy for which the indications are clear, and whose action is comparatively certain, provided it is administered sufficiently early in the history of the disease. This drug is undoubtedly a specific in most, if not all, of the manifestations of lymphatism in young children, if given before these lymphatic hypertrophies have become firmly established; probably in most cases, we may say, before the fifth year of life. It is ordinarily given in too small doses. To a child five years of age it may safely be given in half-drachm doses of the officinal syrup three times daily. During an acute attack it may be given in ten-drop doses every hour. In the later years of the adolescent period its efficacy, of course, is very much diminished.

In cases III. and IV., as we have seen, the subglottic swelling disappeared by the removal of the enlarged faucial lymphatics. The clinical suggestion here seems quite clear.

The point to which I would give especial emphasis in concluding this paper, is the suggestion that attacks of catarrhal croup in young children are the probable manifestations of lymphatism, which should lead us to immediately place them under the administration of the iodide of iron for the correction of the systemic dyscrasia. Certainly the propriety of administering this remedy cannot be questioned, if these children present still other evidence of lymphatism, such as hypertrophied faucial or pharyngeal tonsils. The further suggestion of the propriety of removing such lymphatic hypertrophies as may be found in the air-tract, need not be entered upon. In the third and fourth cases reported, the removal of the lingual tonsil was immediately followed by the subsidence of the subglottic swelling. Why this should occur I cannot say. The clinical fact was undoubted in each case, and it carries with it its special teaching. This of course applies to both the lingual and faucial tonsils, as well as to a pharyngeal adenoid.

SOME CLINICAL FEATURES OF A FRACTURED FEMUR.

By JAMES KENNEDY, M.D.,

San Antonio, Tex.

Fracture of the shaft of the femur, which is a common enough accident, is yet one in which it is sometimes very difficult, and maybe impossible, to form a correct conclusion as to the kind and extent of injury which the bone has received. I have recently met with two cases of this accident which presented clinical features differing sufficiently from the ordinary, I trust, to warrant publication of the reports which I herewith present, illustrated by cuts for the purpose of making clear their distinctive features.

The first case was that of a boy aged thirteen, who, while riding upon a farm wagon, managed to get his left lower extremity caught in the wheel between the spokes, in such a way that the knee engaged in the angle formed by the spoke and felloe, the leg hanging on the outer side of the wheel, while the thigh and buttock became crowded in between the wheel and wagon-bed. So tightly were the parts held thus, that it became necessary to remove the wheel in order to extricate the poor little fellow from his painful position.

I saw the patient about two hours after the accident occurred, and found the limb somewhat swollen, and marked deformity existed. The usual signs of fracture, such as unnatural mobility, crepitus, shortening, etc., were easily made out. There was evidently considerable violence done to the knee-joint, with a possible rupture of the capsule, for the articular surface of the femur was separated from the tibia by a considerable interval, as determined by palpation. Effusion into the joint occurred later. The lower fragment was directed almost antero-posteriorly, with the fractured end lying against the anterior surface of the shaft, while the upper fragment had descended into the popliteal space.

A diagnosis of transverse fracture in the lower third of the femur was made. While the patient was still under the influence of chloroform, the fracture was reduced by first bringing the lower fragment into its proper relations with the knee-joint, maintaining it there, and by extension and manipulation bringing the broken ends into apposition. A temporary splint was applied in anticipation of considerable swelling of the part, which afterward occurred, particularly at the knee. I determined to put the limb up in plaster as early as would be compatible with safety to the part.

Three days later I visited the patient (who lived out in the country), and found that displacement had occurred,

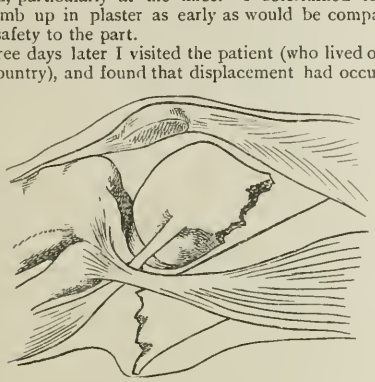

Fig. 1.—Before any Attempt was Made at Reduction.

and notwithstanding the œdema, which was considerable, I put the limb up in plaster, after having again reduced the fracture, for its more thorough immobilization.

Several days later I found, by the amount of shortening which existed, that displacement had again occurred. The limb was once more reduced (each time under chloroform), and plaster-of-Paris, combined with extension, applied.

Two weeks later I found by measurement that shortening to the extent of two inches existed. On removing the dressing and examining the limb, there was complete absence of mobility at the site of the fracture, and there appeared to be perfect continuity along the anterior surface of the shaft. Posteriorly there was a small round ulcer near the margin of the tendon of the biceps, and a hard lump was found under this and lying within the

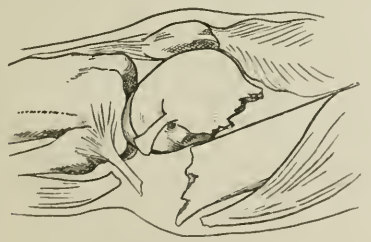

Fig. 2.—Nature's Attempt to Repair Damage.

popliteal space. The harsh grating sensation imparted to a metallic probe left no doubt as to the character of this lump. I decided to place the boy in the hospital and cut down upon the part in order to ascertain the exact condition of affairs, and resort to such measures as would contribute toward the restoration of the limb.

It was plain that, even if I left him with his two inches of shortening, the knee-joint would be useless, because flexion could not be executed so long as this mass of bone remained where it was. I made a free incision along the outer border of the tendon of the biceps, about four inches in length and extending down to the bone, separating the soft tissues and exposing the part. The hard lump in the popliteal space was nothing else than he lower end of the upper fragment; it was necrosed for about an inch, extending upward from the broken surface. The bone had broken in an oblique direction, the fragments had failed to unite, and the spasm of the muscles had forced them out of their proper relations, the obliquity of the surfaces greatly facilitating the displacement. The oblique surface of the lower fragment lay against the anterior surface of the shaft, and was bound to it by a rather firm fibrous union from which it was with difficulty separated, a bone elevator being used to tear them apart. Figure 2 represents the condition found. Figure 3 represents the parts after the operation. The dead portion of the bone was cut off and trimmed in such a way as to facilitate approximation of the surfaces. The lower fragment was freshened by scraping, the surfaces brought together and so maintained. Irrigation with bichloride of mercury, a drainage-tube inserted, the wound closed and antiseptically dressed completes the story of the operation. A useful limb, with a supple knee-joint and one inch of shortening, is a record of the result.

My second case was that of a man about thirty-eight years of age, a robust mechanic, carpenter by trade.

While employed in the construction of a two-story stone building to which there was a cellar, the supports to the second floor gave way under the pressure of several tons of stones which had been piled there for the convenience of the stone-masons, and he with eight other workmen fell from this insecure platform down into the cellar, some thirty feet below, and all of them were more or less buried beneath the débris of stones and timber.

When I first saw the patient his lower extremities were

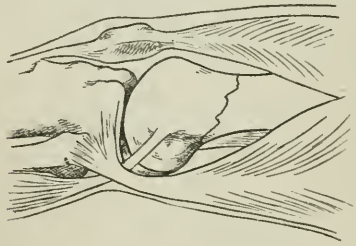

Fig. 3.—Results of Operation.

more or less completely buried in a mass of huge stones which reached as high as his girth. His escape from instantaneous death was almost miraculous, for only a few feet from him lay the lifeless remains of a Mexican laborer crushed almost to a pulp. The vigorous use of a crowbar was required to remove the massive rocks that were piled upon the unfortunate man's extremities. I fully expected to find both of his lower limbs in such a mangled condition as to make a double hip-joint amputation an imperative necessity. In this, however, I was most fortunately disappointed, for the only injury his extremities sustained was a fracture of the shaft of one thigh-bone (right); and I may here add that with the exception of his back being badly bruised, his nose broken, and his face slightly lacerated, no other injury was sustained.

I had him removed at once to the hospital, and there, with the assistance of three other physicians, anæsthetized the patient and examined the limb. This examination proved very unsatisfactory, both on account of the great development of the muscles and the frequent involuntary contractions which occurred, even during profound anæsthesia.

A diagnosis of a simple transverse fracture of the femur at the junction of the middle and upper third of the shaft was made, but I could not fully concur in this, although I could not elicit any certain evidence to the contrary.

That which caused me to doubt the correctness of the diagnosis of my confrères was the ease with which the opposed surfaces of the fragments appeared to glide upon each other after reduction had been effected, and gave

the impression that they did not perfectly approximate during complete relaxation. However, it was decided to approximate the fragments as perfectly as possible, immobilize, and apply extension.

In a few days it was found that displacement had occurred, as evidenced by the four inches of shortening which had taken place, notwithstanding the twenty pounds of extension weight. Chloroform was administered and the fragments again brought into apposition, and plaster of Paris combined with extension applied and left for a week. At the end of this time the limb was measured and found to be three inches shorter than its fellow, which of course meant that displacement had again occurred. The apparatus was removed and the thigh examined. The fragments were found overlapping laterally. I concluded to cut down upon the part as I had done in the preceding case, discover the true condition, and proceed according to the indications thereafter. An incision of about six inches in length was made through the vastus externus muscle, and the injured bone freely exposed. The fragments were found overlapping, the lower one riding the external surface of the upper, and a callous-like material thrown out around the broken ends of the bone. Several comminutions were discovered. The comminuted fragments were completely enveloped in this new formation, and were removed with difficulty. They did not closely approach each other or the main fragments. The lower fragment was drawn out through the wound and exsected. This procedure made the comminutions accessible, and they were withdrawn. The upper fragment, on account of its shortness and the close relation to the hip-joint, was exsected with some difficulty. The fracture was comminuted and *not transverse;* the larger comminution split obliquely both upward and downward from the fractured shaft, extending farther along the upper than the lower fragment. The exsection of this was done at a point which represented but two-thirds of the circumference of the shaft. The object of making the section at this place was to secure the minimum of shortening, and at the same time to leave the bone of sufficient thickness for the support of the body weight and for locomotion. The fragments were then brought together and held with their freshened ends opposed, by means of silver wire passed through both pieces and the ends fastened together. The usual antiseptic precautions were taken throughout. It is now ten weeks since the operation. The limb is two and three-fourths inches shorter than the one of the opposite side, the fragments have united quite firmly, and the patient can sustain almost his entire weight upon the limb without accident or discomfort.

In cases of fracture of the shaft of the femur occurring in individuals in whom the muscles are flabby or but moderately developed, and who possess but a moderate amount of adipose tissue, mistakes as to the exact character of the injury, I presume, will rarely be made if the examination be conducted during anæsthesia. But on the other hand, when the muscles are powerfully developed, or when there is much œdema, or the patient is very obese, it may be quite impossible to determine accurately the character of lesion which the bone has sustained.

A word with reference to shortening in cases of fracture of the thigh, while having no bearing whatever upon the cases herein reported—as they do not represent this feature in its usual relation to this injury—may still not be irrelevant. Since the vast majority of complete fractures are more or less oblique, it seems to me that this fact furnishes the key to the solution of this question, and shows the necessity of neutralizing the spasm of the muscles by a sufficiency of extension properly applied. It is easy to perceive with even a slight obliquity how partial or complete displacement is greatly favored. The oblique surfaces representing inclined planes offer, of course, much less resistance than flat surfaces. I do not underestimate the value of immobilization, but merely suggest that in many cases this is impossible without the aid of adequate extension. It is quite probable that in those cases where manifest shortening (a half-inch or over) occurs, that the fragments have united in a partially displaced condition. In a certain proportion of cases this may be due to imperfect reduction, but it is my opinion that, in the majority of cases, it is the result of a partial displacement produced by muscular spasm, and directly attributable to inefficien extension.

Thes hortening due to imperfect reduction ought to be detected by carefully measuring the limb after setting it, whereas the shortening due to partial displacement after reduction, where insufficient extension has been applied, occurs slowly, and unless the limb be measured not only at the time it is set, but daily for a few days afterward, a considerable amount of remediable shortening may escape detection until it is too late to correct it.

Referring again to the case of the little boy, it will be remembered that the lower end of the upper fragment was, at the time of the operation, found to be increased for about an inch. This fact appears to me to have a special significance, since it does not seem reasonable that, with no serious damage to soft structures, this portion of the bone could have been killed by the injury. I believe that if we could have succeeded in keeping the fragments in apposition, they would have united in the way usual to fractures, and no death of bone would have occurred. Nature, it seems, had no use for this portion of the bone, and attempted to get rid of it by starving it to death, and directed the energies of nutrition toward the union she sought to establish, and with which I interfered, it is to be hoped, for the greater benefit of the patient.

NOTES ON THE THERAPEUTICS OF CROUPOUS PNEUMONIA.[1]

By H. L. JENCKES, M.D.,

HAZEL GREEN, WIS.

The writer will not occupy time by referring to the history or the etiology of croupous pneumonia; these can be found in any of the late text-books. It is also impossible to go over the whole field indicated by the title I have chosen for this paper. The different varieties of pneumonia will not be touched upon, and mention will only be made of some of the more recent remedies which have been employed and advocated as markedly beneficial in the treatment of this disease. Pneumonia is generally easily recognized by the initiatory chill, the pain, prostration, and cough. The temperature is elevated, and the expectoration is streaked with blood. Breathing is not only difficult but rapid. The pulse in severe cases may be small and weak, but this is chiefly because the left heart does not receive enough blood from the lungs to fill its chambers and to distend the arteries. There is dulness on percussion over the inflamed lung, and auscultation frequently reveals fine crepitant râles.

Numerous and various have been the means employed to cure or abort this inflamed and engorged condition of the lungs. The treatment was sanguinary and heroic prior to 1850, but since that time it has been expectant, symptomatic, or specific; this last, or specific treatment, being based on the existing knowledge of germs and their relation to the production of disease. Yet in a careful review[2] of one thousand cases of pneumonia treated in the Massachusetts General Hospital from 1822 to 1890 Drs. Townson and Corledge conclude that the mortality has remained the same under the various methods of treatment which were employed, and that treatment has not influenced the duration of the disease nor its convalescence.

Certain facts, however, regarding its natural history, its tendency in the majority of cases to recovery, and the occurence of crisis or lysis at any time from the fifth to the tenth day have been fully established.

[1] Read before the Dubuque, Ia., Medical Society, June 16, 1891.
[2] The Year-Book of Treatment, 1891.

Among the able contributions on the treatment of pneumonia which appeared during 1890, mention may be made of that of Drs. Sturges and Coupland.[1] Recognizing a natural tendency of the disease to recovery, they discard all thoughts of a specific for pneumonia, and limit the treatment to the control of certain symptoms, such as the alleviation of pain by opium or some of its derivatives, and the securing of sleep by some of the hypnotics, especially by chloral. The control of temperature when high is often a difficult task. Clinical experience has proven that the so-called antipyretics are unsafe on account of the cardiac depression they produce. And in a disease like pneumonia, where there is great pulmonary and venous engorgement, it seems not only necessary but imperative to sustain the action of the heart, and also to relieve the engorgement of the venous system. Sponging the surface with cool or tepid water is generally grateful to the patient, although the temperature is but slightly affected.

With the application of ice to the affected side I have had no experience. The benefit, if any, which results from this is owing probably to the general reduction of the fever and not to any specific influence it has over the localized inflammation. I am inclined to attribute an antipyretic effect to calomel when given in this disease. I have repeatedly seen a fall of one or two degrees after the thorough action of a couple of three- or four-grain doses of the submuriate of mercury. The contents of the bowels are swept out, together with a quantity of bile; in fact, the biliousness so generally present is relieved. The coating upon the tongue begins to disappear, and the heat and dryness of the surface is replaced by a refreshing moisture.

Returning now to a remedy which of late has been advocated as having a destructive, or at least an inhibitory, action on the pneumococcus. This is ethyl iodide. For the action and effect of this remedy I am indebted to an article[2] by Professor Bartholow, who in writing on this subject says: "The influence exerted by it on the cough, the labored breathing, and the general *malaise* is a remarkable fact. It has the single advantage that no apparatus is required, it vaporizes at ordinary temperature, it causes no irritation of the mucous membrane, and it does not act as an anæsthetic. The cases in which it was used were all apparently much benefited by its inhalation, and all expressed a sense of relief to the general *malaise*, and to the specific symptoms—cough, bronchial irritation, and expectoration—the last mentioned being soon changed in character and in quantity."

In the few cases in which I have had patients inhale this remedy, it has sustained the statements made for it by the distinguished writer whose article has been referred to. In studying the pathology of this disease we find from the hepatized and engorged condition of the lungs that there is great obstruction to the pulmonary circulation, and greater amount of work is necessarily demanded of the right heart. As the blood accumulates and distends the venous system there is a corresponding depletion of the arterial system. The rational indications for therapeutical interference would then be to relieve the engorged lung, to restore the equilibrium of the circulation by transposing a quantity of venous blood to the arterial system, and finally to sustain the action of the heart.

This brings us to a very able paper "On Acute Obstructive Diseases of the Lungs," read by Dr. Andrew H. Smith at the Tenth International Medical Congress, In this paper[3] the writer forcibly expresses the indications for treatment when he says: "Increasing obstruction with decreasing right heart power means death; decreasing obstruction with sustained right heart power gives promise of recovery. It is a question with which the left heart has almost nothing to do, for the peril is not from general exhaustion, as, for example, in fever, nor from failure of the heart as a whole, as in some cases of infection; but specifically from tiring out of the right heart in its effort to unload the venous circulation through the obstructed vessels of the lungs."

The logical conclusion to be drawn from this is to administer remedies that relax the arterial system, and by increasing its capacity we relieve the veins proportionately; and by diminishing the venous engorgement we relieve the respiration and lighten the labor of the right heart. Among remedies that relax the arteries may be mentioned aconite, alcohol, and especially the nitrites of sodium or potassium. And regarding nitro-glycerine, which also possesses this property, Dr. Smith says: "Again and again I have seen a patient with pneumonia somnolent, or even comatose, with the face gray, the lips livid, the respiration superficial and from 50 to 60 per minute, and the chest everywhere full of moist râles, but nevertheless rescued from this apparently hopeless condition by drop doses of a one per cent. solution of nitro-glycerine administered every fifteen or thirty minutes."

In an editorial comment on this paper which appeared in the MEDICAL RECORD[1] the writer, after a short discussion of the paper, says: "Dr. Smith's contribution to the therapeutics of pneumonia is the best that has been made for years, yet he makes no allusion to antipyretics or baths." The inhalation of oxygen certainly gives the patient that element of the air which he particularly needs in all cases of obstruction to the respiration, and in all grave cases can be given with benefit. Digitalis, which is so frequently given in this disease, is mentioned only to be condemned. Nor is Dr. Smith alone in this opinion, for Loomis says that in pneumonia digitalis does more harm than good. By its powerful action on the left ventricle a still greater quantity of blood is forced into the already overloaded venous system, thereby defeating one of the main conditions aimed at in treatment, the relief of the pulmonary and venous engorgement and the equalization of the circulation.

In summarizing the conclusions to be drawn from this brief paper we would say:

In the beginning of an attack of pneumonia, and especially when biliousness is present, marked benefit will be experienced by the administration of a few small doses of calomel. Let ethyl iodide be freely inhaled, not only for its supposed specific effect upon the pneumococcus, but also because of the relief it affords the pulmonary symptoms. In all severe and particularly grave cases with the free use of alcohol let the patient also receive the nitrite of sodium or a one per cent. solution of nitro-glycerine. Should these fail in their intended action to relieve the embarrassed circulation, and the patient being robust and plethoric, he may be carried over a critical period by the abstraction of twelve or sixteen ounces of blood.

The Medical Profession in Austria.—According to official statistics which have recently been published, the total number of medical men in Austria at the end of 1889 was 7,146, of whom 5,358 were Doctors of Medicine and 1,788 practitioners of a lower grade (*Wundarzte*, surgeons). The proportion of doctors to population was highest in the district of Trieste, where it was 61.7 per 100,000, Lower Austria being second with a very slightly lower ratio, and the Tyrol and Vorarlberg coming next at no great distance. In the other provinces the proportion was much smaller, being about thirty per 100,000 in Salzburg and Steiermark, and falling as low as 5.9 in Krain, 3.7 in Bukowina, and 3.2 in Galicia. As might be expected, the Doctors of Medicine most do congregate in the large towns, while the lower-grade practitioners most affect the villages and rural districts. About twenty-one per cent. of the Doctors of Medicine practise in Vienna.—*British Medical Journal.*

THE USE OF THE ELECTRO-MAGNET TO EXTRACT BURIED PARTICLES OF IRON OR STEEL FROM THE TISSUES.

By CHARLES CLIFFORD BARROWS, M.D.,

NEW YORK.

The use of the magnet for the purpose of extracting small fragments of needle buried in the tissues has been suggested by most writers on surgical subjects. It has, however, rarely been applied with success because the ordinary magnet has not power enough to exert much influence over so minute a particle of steel when this lies deeply buried in the muscles or cellular tissue. Small pieces of fine needles thus embedded are at times extremely difficult to locate accurately, and still more difficult to extract, except by a cutting operation altogether out of proportion in magnitude to the object sought.

It is always desirable to extract foreign bodies of this kind, because if left to themselves their tendency is to travel more deeply into the tissues and to give rise frequently to serious trouble, such, for instance, as necrosis of the bones dependent on periostitis provoked by the presence of such an irritant.

In illustration of the advantage of the electro-magnet for the purpose of extracting from the tissues foreign bodies of this character the following case serves a good purpose :

On September 4th, Mrs. B—— brought her little daughter, Margaret, down from her country place on the Hudson, to consult me about the removal of a piece of cambric needle from the child's right thumb. On the day previous to her coming to me she had broken off in the ball of her right thumb about an eighth of an inch of the length of a fine sewing-needle. The child had attempted to extract it herself with the point of a pair of scissors, but had only succeeded in driving it deeper into the tissues. She was then taken to the local physician, who attempted to remove the fragment, but without success. At his suggestion poultices were applied to the thumb to draw the needle out. As the needle declined to be drawn out by the poultices, on the following day the mother brought the child to me.

On examination I was able to locate the needle by the sensation of pain it produced on pressure over the point of entrance, which had been considerably enlarged by the various efforts at extraction. I could not, however, reach it or seize it with the finest-pointed forceps. The repeated attempts at extraction had made the thumb very tender, and had well-nigh exhausted the child's patience.

I then determined to try the effect of a very powerful electro-magnet, feeling sure that no ordinary magnet would have the slightest effect on so minute a particle of steel so deeply sunken in the muscles of the thumb. I took the child into the office of the Edison Electric Company, which happens to be near my office.

Mr. Hadley, the manager, very kindly connected up for me a very powerful electric motor, and permitted me to use the electro-magnet which constitutes a part of the machine. By placing the child's thumb against the pole of the magnet, and gently kneading the tissues, the fragment of needle was drawn up so that it could be felt with a sharp-pointed instrument in the bottom of the small wound. A piece of soft iron with a sharp point was then placed in contact with the pole of the powerful electro-magnet, thus be-magnetized, and the point was brought into apposition with the end of the piece of needle, bringing the fragment with it as it was withdrawn. This procedure was entirely painless.

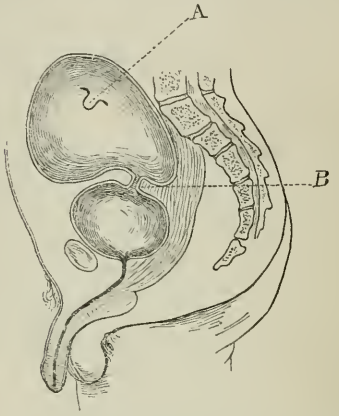
An Ohio Doctor, who had worked hundreds of cures with his liver medicine, owned up the other day when dying that his "remedy" was of no earthly good in a real case, but that he simply worked on the imagination. He says a man who won't believe in anything else will believe that his liver is out of order.—*Times and Register.*

CONGENITAL MALFORMATION—ATRESIA ANI-VESICALIS, WITH AN ANATOMICAL PECULIARITY NOT HERETOFORE DESCRIBED.

By J. M. SLIGH, M.D.,

GRANITE, MONT.

On August 29, 1891, I delivered Mrs. L. J. F—— of a male child weighing eight pounds, and apparently healthy. On the evening of August 30th the nurse reported that the child's bowels had not moved, and I directed her to administer an enema. The following morning the father came to my office saying the nurse could not give the enema, as she could find no opening



to the bowel. Going to the house and examining the child I found a case of imperforate anus, upon which I operated at once by a crucial incision between the base of the scrotum and the coccyx, carefully dissecting between the bladder and sacrum for a distance of two and one-fourth inches without finding any rectum. I advised the father that it was useless to explore further, and that the child must die or take its chances of living through a laparo-colotomy, which latter proceeding he declined. The next day the nurse informed me that the child's urine was high-colored, thick, and smelled like a passage from the bowels, when I was satisfied that it was a case of atresia ani-vesicalis. From this time the child vomited frequently, and died on the night of September 3, 1891.

On the morning of September 4th I made a post-mortem examination. The abdomen was largely distended. Upon going through the peritoneum, there presented in the wound a body which nearly filled the abdominal cavity, and which I was at a loss to account for, but which I supposed might be an enormously distended stomach or bladder. Getting it out of the abdomen I was enabled to find the stomach and bladder in proper positions, and normal in appearance, except that the bladder was considerably distended. The small intestines, ascending and transverse colon were normal, but there was no descending colon or rectum. Where the descending colon should have been was a large sac or pouch into which opened the transverse colon by a valvular orifice somewhat smaller in diameter than the transverse colon, and which was the strange body that first presented in the wound. This sac or pouch was filled with semi-liquid fæces, and was the cause of the abdominal distention, its capacity being at least three fluid ounces. Its only attachments were at the opening into it of the transverse colon and a counter-opening from it into the posterior aspect of the fundus of the bladder, through a tube one-half inch in length with a lumen of about one-tenth inch diameter. The walls of this pouch were thick, and its mucous surface was thrown into small folds, or rugæ, presenting somewhat the appearance of an hypertrophied

adult bladder. The distention of the bladder was caused by the presence in it of fæces, differing only from those in the pouch by being somewhat thinner and lighter in color, due to admixture of urine.

This case differs from any other kind of this character of malformation I have ever seen, in the fact that the descending colon and rectum were absent, being replaced by a large pouch with very thick walls and its mucous membrane thrown into rugæ or folds. The anus is absent, and the transverse colon has a valvular opening, *A*, into a sac or pouch of about three ounces capacity, this in turn opening into fundus of bladder, on posterior side, through a duct half an inch in length, and one-tenth inch in diameter, *B*.

Clinical Department.

SOME ABNORMAL EYE SYMPTOMS AS A DIAGNOSTIC AID TO OTHER DISEASES.[1]

By RICHARD H. SATTERLEE, M.D.,
NEW YORK.

Attention to the eye symptoms will often result in a physician looking for other signs, and this may lead to the detection of a state of affairs hitherto unsuspected.

Œdema of the lids is often the first thing noted in the examination of a patient. This may mean conjunctivitis, a premonitory symptom of coryza, the simple fevers, hay fever, arsenical poisoning, some lesion of the heart, lungs, or kidneys. When administering arsenic this œdema is a valuable sign as showing that the drug is being given in excess of the bodily powers to eliminate.

Styes show an anæmic or strumous condition, or derangement of the digestive apparatus or organs of reproduction. They are also found in certain forms of eye strain. The same conditions that produce styes may cause that chronic inflamed condition of the lids termed blepharitis marginalis.

Ptosis, while due to inflammation of the lids, tumors, or erysipelas, is also frequently indicative of brain lesion with paralysis of the third nerve.

Blepharospasm may occur during mental excitement or an epileptic seizure; it may also be found in chorea and hysteria.

Marked protrusion of one eye would probably mean a new-growth in the orbit, of both eyes exophthalmic goitre. Inability to move the eye outward would lead one to suspect paralysis of the sixth nerve. Paralysis of the sixth with hemiplegia of the opposite side points to a lesion at the pons Varolii—usually on the same side as the eye affected.

The fixed stare of some forms of hysteria and insanity are well known; also the rolling of the eyes during convulsions and approaching dissolution.

The cornea and conjunctiva are often red and injected, or have a peculiar appearance. In diphtheria the membrane sometimes forms here, though rarely. The reddish appearance in hay fever, scarlet fever, measles, and from an overdose of the iodides is familiar to all of us. Phlyctenules show a depraved condition of the system and improper diet. Painless ulcers on the cornea generally indicate a lesion of the fifth nerve. In jaundice the conjunctiva becomes of a brownish hue, in Addison's disease it looks lustreless and dark-colored.

Arcus senilis in the young or middle aged is often an accompaniment of fatty heart or fatty degeneration of other organs.

Nystagmus—that rapid involuntary movement of the eyes—is a sign of third- or sixth-nerve paralysis, or a premonitory symptom of disseminated sclerosis. It is also found where the eyes are of unequal refraction.

The pupil should be carefully watched. It is dilated in hysteria, hypochondria, lead-poisoning, hydrocephalus, paralysis of the third nerve, reflex irritation from seat worms, and after the administration of large doses of the following drugs: aconite, salicylic acid, strychnia, belladonna, cannabis indica, conium, duboisia, digitalis, ergot, hyoscyamus, quinine, lobelia, pulsatilla, veratrum viride, santonin, stramonium, nitrite of amyl, and gelsemium. The dilated pupil during chloroform narcosis is a danger signal.

The pupil is contracted in all early stages of brain disease, cholera, intracranial tumors, cerebral apoplexy, and all lesions of the brain or spinal cord above the dorsal vertebræ. Opium, jaborandi, tobacco, physostigma, carbolic acid, calibar bean, and chloral hydrate all contract the pupil when given in large doses. The pupils being of unequal size is almost certain to be a precursory sign of insanity. If the pupil does not react properly, and the iris is slightly altered in color, you have an iritis of syphilitic, rheumatic, or gouty origin. Post-partum or any other severe hemorrhage may be followed in from two to fifteen days by loss of eyesight, which is not usually regained.

Subjective Symptoms.—The patient complaining of the eyes becoming easily fatigued may be the first symptom calling your attention to a general anæmic condition. If complaint is made of only seeing half an object, look for beginning paralysis with a lesion or tumor of the brain.

In many cases of parametritis and pelvic cellulitis the eyes are easily fatigued, accompanied by orbital pain and more or less sensitiveness to artificial light.

In spinal disease the patient is apt to have diplopia, photophobia, muscæ volitantes, and undue retention of after images.

Loss of accommodation is often present in pathological irritation of the dental branch of the trigeminus, a spur on the nasal septum, intestinal irritation from worms, diseases of the stomach, liver, or intestines, and during convalescence from diphtheria.

A LARGE DOSE OF PARALDEHYDE.

By J. NOER, M.D.,
STOUGHTON, WIS.

On August 18, 1891, at about 6 P.M., while on my way home for supper, I was accosted by one J. H——, who desired me to give him something to put him to sleep. He declared that he had not slept for ten days. Knowing him to be a man who was very much addicted to the use of liquor, I concluded that he was on the verge of delirium tremens. I handed him the following prescription:

℞. Paraldehyde..... gm. 10
Syr. aurantii cort..... gm. 30
M. S.: Shake bottle and take one teaspoonful every half hour till sleep is produced.

At 9 P.M. same day the druggist called on me with the bottle which had contained the above mixture, desiring to know if it would be safe to refill, patient having sent down for another bottleful. I of course replied no, and started for the home of my reckless patient.

I found him in bed, wide awake, and in a very happy frame of mind. He had taken the whole amount at once, he said, but added that he thought he needed about a quart more.

Aside from a slight delirious tendency and a little quickening of the pulse, the paraldehyde had produced no visible effects. I gave him three grammes pot. brom. in water, and left two powders of the same, containing one and one-half gramme each, to be given one every hour if not quiet; next morning I found him calm and rational. He had taken all the bromide, after which about two hours' sleep had been obtained. His breath smelt very strongly of paraldehyde, but in every other way he was apparently in a much better condition than in the evening before taking the medicine. As the maximum dose of paraldehyde is four grammes, or one drachm, I thought the case worthy of consideration as showing an unusual toleration of the drug.

INCESSANT HICCOUGH RELIEVED BY LAVAGE OF THE STOMACH.

By EVERETT J. BROWN, M.D.,
DECATUR, ILL.

READING in the daily press lately several accounts of a most persistent case of hiccough which had lasted many days and which was baffling the skill of the local medical fraternity, recalls to my mind a case of the same trouble which came under my care while a resident physician in Cook County Hospital, Chicago, of which case I find I have complete notes:

S. S——, a Russian peddler, aged twenty-seven, admitted to hospital April 30, 1888. Had always been in good health; on admission complained only of a persistent and incessant hiccough, which continued night and day; it had already lasted one week; he was thoroughly exhausted from loss of sleep and the pain and soreness produced by the constant contractions of the diaphragm; the usual remedies for these cases, such as morphine, bromide and chloral, ether, cannabis indica, bismuth, soda, and atropine, were each tried, but with little or no effect; morphine in large doses would relieve for one or two hours and allow the patient some sleep; electricity applied to the epigastrium and to the phrenic nerve was of no avail.

On examination over the region of the stomach that organ was found to be considerably dilated and to contain a large quantity of fluid; there were no external signs of a tumor or other pyloric obstruction; thinking that the dilatation of the stomach and the retention of fermenting food might be a cause of the hiccough I introduced a siphon-tube into the stomach and thoroughly washed out that organ; at least two quarts more of fluid were removed than had been introduced through the tube, and that which was removed was in a high state of fermentation. After this operation the hiccough entirely ceased and the patient had his first good night's sleep in sixteen days. He was discharged two days later with no return of the trouble.

THE VARIABLENESS OF ASTIGMATISM FROM CATARACT OPERATIONS.

By S. MITCHELL, M.D.,
HORNELLSVILLE, N. Y.

I THINK all who have had any experience with the astigmatism that is produced by cataract operations, have come to the conclusion that such astigmatism is not, like the law of the Medes and Persians, changeless, but, on the other hand, is exceedingly prone to variations. However, I never consider that I have assisted my cataract patients to the very best vision attainable until I have tried cylindrical lenses, and always prescribe them when an improvement is to be gained thereby.

In my experience, I find that the majority of eyes are, by the operation, made astigmatic for a time, and by far the greater part of these require the axis of the cylindrical lens to be placed horizontal or approximating to it.

The following case illustrates this variation in a very marked manner:

Mathew W——, aged seventy-nine, an Irish gentleman from a neighboring town, had his left eye operated upon for cataract by me, March 20, 1890. I was obliged to perform iridectomy on account of the unyielding condition of the iris.

The eye did nicely, and my patient returned to his home ten days later with $\frac{20}{100}$ vision. I did not attempt to fit a glass at this time, as he had $\frac{20}{50}$ vision in the right eye, which had been operated upon by Dr. Hubbel, of Buffalo, one year previous.

Five weeks later, V. L. E. with + 8 D.+ 5.50 D. cyl. axis 180° = $\frac{20}{50}$. I did not order this glass, but thought best to wait a short time before so doing.

Six weeks later, V. L. E. with + 10 D.+ 2.75 D. cyl. axis 180° = $\frac{20}{40}$. This glass has been worn with perfect satisfaction until very recently, when my old friend again called on me, and speaking of his eyes, which he facetiously designated as his "Buffalo eye" and his "Hornellsville eye," he informed me that he was not seeing as well as formerly with his "Hornellsville eye." I now found that V. L. E. was $\frac{20}{100}$ with the glass he had been wearing, but with + $\frac{1}{8}\frac{0}{0}$ D. spherical it was raised to $\frac{20}{30}$ (—), thus showing a variation in the refraction of the eye that to me was quite remarkable.

OFFENSIVE LOCHIA DUE TO LACERATION OF THE UTERINE AND VAGINAL TISSUES, WITH NO RISE IN TEMPERATURE.

By C. S. SCOFIELD, M.D.,
BOSTON, MASS.

IN the MEDICAL RECORD of September 12th, under the heading of "Fetor of Lochial Discharges," Dr. Baxall states that it may occur with or without a rise in temperature. About two weeks ago I attended in confinement Mrs. R——, primipara, nineteen years of age. The labor was normal, except that the second stage was protracted by reason of rigidity of the perineum. Fortunately, however, after considerable delay delivery was accomplished and the uterus was emptied of placenta and membranes, with no tear in the perineum. On visiting my patient the following day, the nurse called my attention to the fetor of the lochia. There was no rise in temperature except on the third day, when milk first appeared, and although the odor continued until the ninth day, Mrs. R—— experienced no trouble from it and made a good recovery. This case supports the statement of Dr. Baxall, that fetor may be due to lacerated tissues, and may occur with no rise in temperature.

I will also state that I directed the nurse (one of experience) to give antiseptic vaginal injections three times daily, and to apply antiseptic pads to the vulva after each injection. I have had great faith in the injections and pads since I first used them, in the summer of 1882, while attending an out-patient of the Boston Lying-in Hospital, a report of which I sent to the Hospital at the time. The case developed puerperal fever, and to get rid of the offensive odor of the lochia I gave hot carbolized vaginal injections, and had napkins wrung out of the solution and applied to the vulva, keeping them in place with a dry one pinned in front and back to the bandage. The odor entirely disappeared in a short time, the temperature went down, and the woman made a good recovery. Had I reported the case to one of the medical journals, I think it would have been the first reported case of antiseptic pads so used in obstetrics.

Lumbago and Lumbar Sprain.—In an article contrasting these two conditions, published in the *University Medical Magazine* for November, 1891, Dr. S. W. Latta gives the following table of the diagnostic differences:

Lumbago.	*Lumbar Sprain.*
Duration, five to ten days.	Duration, fourteen to twenty-eight days.
Onset, sudden.	Onset, instantaneous.
Cause: Predisposition; rheumatic or gouty diathesis; exposure to cold and wet; overfatigue or slight strain of muscles in one having a predisposition.	Cause: Injury by twist, fall, direct force, or from overlifting.
Pain: Tearing or aching, confined to a single or group of muscles; aggravated by movement.	Pain: Acute, lancinating, and diffused; slight movement causes agony.
No outward signs.	Local heat, swelling, ecchymosis, and discoloration.
Rarely painful to touch; pinching affected muscle may elicit pain.	Excessive local tenderness.
No particular decubitus.	Decubitus on *either* side, with knees drawn up toward chin.
Heat aggravates.	Heat is grateful.
Constitutional symptoms not common.	Constitutional symptoms nearly always present.

Progress of Medical Science.

The Simultaneous Existence of Two Substances in Cultures of Staphylococcus Pyogenes. — Drs. Rodet and Courmont presented a note at the Académie des Sciences on the simultaneous existence in the cultures of staphylococcus pyogenes of a vaccinating substance precipitable by alcohol, and of a predisposing substance soluble in alcohol. The effect of the vaccinating substance is completely masked in filtered cultures by that of the predisposing substance. Heating for twenty-four hours at a temperature of 55° C. may make it appear. The indication is thus given to attempt the isolation of a vaccine from the soluble products of a pathogenic microbe which does not appear to fabricate one normally.—*La France Médicale.*

Meningo-Myelitis of Gonorrhœal Origin.—Meningomyelitis of blennorrhagic origin was first studied by Hayem and Parmentier, who observed and published two cases. Charcot and Jarochewky have each observed a case since this time. Charcot, contrary to the opinion of the earlier observers, looks upon the affection as indirect, that is to say, that the medullary symptoms are only the consequence of irritation of the nerve-terminations in the articulations which are affected with the gonorrhœal arthritis. Dr. Polozoff relates an instance of this rare and interesting condition in the *Roussk Medyc.*, No. 17, 1891, in which the medullary symptoms came on in the absence of any gonorrhœal arthritis. A soldier, six weeks after an acute gonorrhœa, entered the hospital, complaining of weakness in the lower limbs, painful sensations, retention of urine, and constipation. Examination showed a paralysis of the limbs, accompanied by difficulty in walking, and trembling. The lower lumbar vertebræ were painful on pressure, complete anæsthesia was present on both sides, and paræsthesia was also present, along with fulgurant pains. The knee-reflexes were exaggerated. Temperature, normal. This state continued for twelve days. Constipation gave way slowly to injections and purgatives. Micturition remained difficult, and the catheter had to be passed daily.

At this time the temperature rose, the pains became more severe, hyperæsthesia of the skin of the abdomen and lower extremities came on, and a sense of constriction about the waist was complained of in the region of the affected lumbar vertebræ. A month after admission there were tonic convulsions of the muscles of the lower limbs. Obstinate constipation persisted. After two months, atrophy of the muscles of the legs was followed by paralytic phenomena more pronounced. In order to walk the patient was obliged to raise the limbs with his hands, and each time the sole touched the ground the muscles of the legs became the seat of clonic convulsions, and the patient was obliged to rest against some object to prevent falling. The only etiological cause was the gonorrhœa.—*La France Médicale.*

Transformation of Virus.—Dr. Chauveau concludes a work on this subject, read at the Paris Academy of Medicine, as follows: 1. Vaccinal virus never gives variola to man. 2. Variola virus never gives vaccinia to the cow or horse. 3. Vaccinia is hence not attenuated variola and cannot be compared to benign anthrax infection communicated to animals by the inoculation of attenuated anthrax virus. 4. If vaccinia is derived from variola it is by means of a radical transformation of the variola virus, up to the present time beyond the knowledge of experimenters. 5. The attenuation of virus is not an operation that can be identified with transformation.—*Gazette des Hôpitaux.*

Early Operation in Acute Peritonitis.—Dr. Lydston formulates his views on acute peritonitis as follows: 1. I do not believe in the existence of acute idiopathic primary peritonitis. 2. The majority of cases of so-called idiopathic peritonitis in children will be found, upon inquiry, to be traumatic. 3. Slight injuries of the abdominal contents are relatively more dangerous in children than in adults. 4. Acute peritonitis in children, while apparently idiopathic, is often secondary to perityphlitic inflammation, which runs a rapid course and extends to the general peritoneum without the intervention of appreciable local changes. 5. The profound prostration and cardiac inhibition characteristic of peritonitis are in a great measure incidental, (1) to tension of the peritoneum produced by inflammatory products, with a consequent reflex inhibition of the heart, and (2) mechanical interference with the heart's action. 6. Surgical interference is indicated in all severe cases of general peritonitis, and in cases of localized suppurative inflammation, or in cases of perityphlitic origin, whether due to foreign bodies or not. 7. There is every indication present for operation, and no logical objection to it. The operation is almost invariably palliative, if not curative. 8. Operation in no sense impairs the chances of recovery. *Per contra*, it enhances them to a great degree. 9. No case should be allowed to die without operation, unless already *in articulo mortis*. 10. It is not necessary to make a large incision, excepting in cases in which perityphlitic abscess is known to exist, which is rarely the case in children. If perityphlitic abscess exist and is recognized before operation, the incision should be made at the most favorable point, which, in the majority of cases, is the typical line for ligation of the common iliac, as pointed out by Murphy and Lee. In by far the majority of cases in children a simple median exploratory incision, with flushing of the abdominal cavity, is sufficient.—*Western Medical Reporter.*

The Praise of Drunkenness.—Dr. George Foy sends to the *Medical Press and Circular* the following letter, which ought to be of extreme interest in connection with the present agitation on the subject of drinking. Dr. Foy writes: "As an evidence of the altered social habits of the general public, I wish to bring a curious old volume under the notice of your readers. It was printed for E. Curl, against Catherine Street, in the Strand, London, in 1723, and is marked 'Price Five Shilling.' The title is as follows: 'Ebrietatis Encomium, or the Praise of Drunkenness; wherein is authentically and most evidently proved, the NECESSITY of frequently GETTING DRUNK; and, that the PRACTICE of getting DRUNK is most ANTIENT, PRIMITIVE, and CATHOLIC. Confirmed BY THE EXAMPLE of *Heathens*, *Turks*, *Infidels*, *Primitive Christians*, *Saints*, *Popes*, *Bishops*, *Doctors*, *Philosophers*, *Poets*, *Freemasons*, and other *Men of* LEARNING *in all Ages*. By Boniface Oinophilus, de Monte Fiascone, A.B.C.'

> 'Vinum reficans cor hominis,
> Narratur et Prisci Catories,
> Sæpe mero caluisse virtus.'—HORAT.

"The author lays down the following rules for getting drunk, to wit: 1. Not too often. 2. In good company. 3. With good wine. 4. At convenient times. 5. Force no one to drink. 6. Do not push drunkenness too far. The volume ends with a postscript by F. Sans-Terre, dated May 1, 1723, '*From my Garret in* Bandy-legged Walk.' A year made memorable by the death of 'Vanessa.'"

Cocaine in the Urethra.—Dr. E. R. Palmer, of Louisville, referring to an item in a recent issue of the MEDICAL RECORD, to the effect that the use of cocaine in the urethra is attended with more risk than in any other part, and that it should be positively forbidden in the recently cut or denuded urethra, writes: "I have used cocaine, in four per cent. solution, in the male urethra daily—frequently a dozen times daily—since 1886. Numbers of these cases have been those in which internal urethrotomy had been done the day before, and I have never seen the slightest ill-effects from its use. My solutions are carefully prepared by my assistant in my own laboratory, and from the best cocaine muriate."

THE TONSILS AS GUARD-HOUSES.

IT is sometimes amusing to witness the efforts of well-meaning men to make plain to the lay mind the *rôle* of bacteria in disease, and to read the articles in lay journals in which some of the facts, and supposed facts, of bacteriology are explained so as to be understood by the people.

An example in point is a dissertation in an English illustrated journal on the tonsils, in which some rather wild statements are made concerning the office of these organs as preventers of disease. After discussing their structure and alluding to some of the guesses as to their function by physiologists (which were about as near the truth as medical guesses are apt to come), the writer comes to the latest supposition, which he seems to regard as an eminently satisfactory one. It is, namely, that the tonsils manufacture the white blood-cells in quantities to meet the demands of the system. Some of these sally forth into the blood and go up and down through the circulatory system like a squad of sanitary police (more efficient, we hope, than some of their human *confrères*), wandering off their beat when necessary to enter the private property of the organs and extra-vascular tissues, or wherever they may find disease-germs to attack and destroy. This is a fairly clear explanation of a plausible and popular theory as regards phagocytosis, but the assumption as to the blood-making function of the tonsils has hardly as yet arrived at the dignity of a truth, and its broad and unqualified statement in a popular journal of wide circulation is not, we think, in the interests of that scientific accuracy which writers for the laity should ever keep in view.

But all the white corpuscles do not make regular rounds, it appears, for many of them simply come out on the surface of the tonsils and there stand guard, like detectives watching for pickpockets at a circus, waiting for the unwary germ to show himself in order to annihilate him, and thus preventing the injurious germs from passing onward to the throat, stomach, and lungs. "This is," the writer says, and we cannot but agree with him, "both an extraordinary and an extremely interesting discovery, for it makes plain to us how and why many of the germs we inhale are prevented from doing injury to us. They may pass into the mouth, but the cordon of white blood-cells on the tonsils acts as a fairly efficient barrier, which the bulk of the germs we inhale may not pass, and we are thus secured from the germ invasion of both the digestive system and the breathing system."

We bow to the phagocytes, for they must indeed be ready of sight and quick of hand to be able to seize a typhoid bacillus as he cavorts gayly in a turbid flood of milk and water rushing between the tonsils, cutting short his dreams of unbridled riot in the intestinal tract. The Indian salmon-spearer of the Northwest might take lessons of the phagocyte that sits upon the tonsil. But the white corpuscle is not a skilful fisherman only, for he can snatch the germ from the centre of a pasty bolus, as well as shoot him on the wing as he spreads his pinions to the northeast gale and flies by with the current to reach a quiet shelter in the pulmonary alveoles.

Now this is nonsense. The French investigator who has urged more especially this theory of the protective *rôle* of the tonsils is doubtless right in a measure. It may be possible that many pathogenic bacteria which become lodged on the tonsils are there destroyed by the white corpuscles, but this is very different from the absurdly exaggerated *rôle* attributed to these glands and to the white blood-cells by the romancer whom we have quoted. We believe thoroughly in lay instruction in the facts of physiology and bacteriology, and we are always glad to see popular presentations of these subjects in the magazines. But such travesties as this can only do harm and should be reprobated, notwithstanding that their perusal in the fresh and solemn original serves to amuse the professional reader, and furnishes a little relaxation to his tired mind.

THE DISCOVERY OF THE VIS MEDICATRIX NATURÆ.

THOSE who have carefully followed the recent and rapid progress in the study of infectious diseases cannot fail to be impressed with a feeling that we are on the verge of discoveries of extraordinary importance to humanity. We do not refer alone to the possible finding of protective "vaccines" for all kinds of diseases. It will always be better to "stamp out" than to vaccinate, and society will eventually adopt the first as the fundamental method. But there will surely come a time when the physician will not have to play the part of spectator while fevers and infections run their course. He will be able to do more than look after the nursing, leaving the rest to the natural resisting power of the organism.

Such is the inevitable conclusion drawn from reading the recently published Croonian lectures of Professor Burdon Sanderson on "The Progress of Discovery Relating to the Origin and Nature of Infectious Diseases."

The results of the labors of numerous modern experimenters have tended to bring us nearer every month toward a definite knowledge of the methods by which the human system fights against disease and is protected against infection. It has been shown that in some cases there develops in the blood a substance which is antagonistic to the life of the specific micro-organism and prevents its development, while in other cases there is developed a substance in the blood which antagonizes the toxic products of the microbe's growth, but does not stop the growth itself. Thus in tetanus the disease is

due to a bacillns which secretes in infinitesimal amount a convulsive poison. The infection is a toxic one. Now, by introducing into the circulation the blood of a protected animal it is possible to antagonize this poison without inhibiting the growth of the microbe. The specific protective agent, or "alexiteric," against tetanus is therefore an antitoxic agent.

On the other hand, in such diseases as splenic fever, rouget or pig erysipelas, the symptoms are accompanied with the production of enormous numbers of bacilli in the blood, and it is chiefly by the multiplication of these that the system becomes overwhelmed and death ensues. The infection is spoken of as "biotic," in distinction from "toxic," and correspondingly the protective agent acts by inhibiting the growth of the bacilli. In other words, the protective or alexiteric action is antibiotic. But it has been found, further, that the protective agents of both kinds are chemical substances which are held in solution in the liquor sanguinis, and are developed probably by the metabolic changes in the tissues.

That this agent is a soluble non-particulate substance was shown in an ingenious way by Emmerich. A rabbit immunerized to rouget was killed and the comminuted tissues subjected to extreme pressure; the juice obtained was filtered through porcelain and collected in sterilized flasks. Dr. Burdon Sanderson says: "When this is injected into the body of a normal, that is susceptible, rabbit it produces no disturbance of any function, but confers upon it an antibiotic state, so that if a sufficient quantity of the liquid is injected immediately after a fatal dose of the virulent culture of rouget, the development of the disease is averted. In such an animal a slight febrile reaction immediately follows the injection, whereas in an animal in which the development of the disease is left to itself the body temperature of the infected animal culminates on the fifth day with a temperature of 100° F. On testing the condition of the blood by plate cultures it was found that, as in the immune animal, there was no multiplication of bacilli. In other experiments, instead of introducing the virus and its antidote simultaneously, the injection of the former (the virus) was deferred for twenty four hours. The result was much the same, showing that the effect continues for some time after the material itself has been discharged from the system, and this inference was confirmed by observing that even after eleven days the effect of a fatal dose was much mitigated, for the disease ran a favorable course ending in recovery."

The lecturer's conclusions from the foregoing studies are impressively put. Dr. Sanderson further says: "We have learned that a substance is contained in the liquor sanguinis, that it acts in relatively small doses, that it is capable of counter-infecting the whole organism, that by combining antibiotic and antitoxic properties in varying proportions it adapts itself to the requirement of the particular infection against which the organism is to be protected.

"How does all this bear on practical medicine? In medicine we have heretofore depended and still depend on the *vis medicatrix naturæ* as the means by which diseases may be cured. It has been proved that the organism possesses the power of bringing into existence certain chemical agents which are the embodiment of the particular *vis protectrix* required, by which the organism guards itself against some of the most important of the specific infections to which it is exposed.

"To have learned this is to have entered on the beginning of a new progress, to have turned over a new leaf in pathology. It seems to me to require no prophetic power to foresee that we are on the very threshold of discoveries in medicine such as will eclipse in their splendor all that have preceded them. Happy are they who are young enough to hope to see this anticipation realized."

SHAMMING FEVER.

We referred recently to certain cases of abnormally high or irregular temperature that had been observed and recorded by reliable observers, and said that the fact that such temperatures had actually occurred was indisputable, if repeated thermometric tests made with every precaution to prevent or detect fraud can be trusted to at all. Many of the cases of supposed high temperature, and which have been recorded as such, are, however, doubtless simulated. A curious little epidemic, it might be called, of malingering of this sort occurred during the past year at Helsingborg, in Sweden, and is recorded by Dr. Ali Krogius, physician to the Surgical Hospital in that city, in the October issue of the *Finska Läkasesälls-kapets Handlingar*.

Four patients in the hospital, three men and one woman, succeeded for a time in either simulating a fever which had no existence in fact, or in causing the thermometer to give a high register to a fever which was present in very mild degree. Their method consisted in rubbing the bulb of the thermometer in the folds of their undergarments, or in tapping with the finger several times on the upper extremity of the instrument so as to shake up the register. The malingerers were no ordinary fools, for they didn't throw the register up to the highest degree every time, but made the temperature curve follow what would ordinarily be seen in a typhoid fever, the evening temperature being always higher than that of the morning of the same day. The fraud was detected by using a thermometer in the rectum at the same time with one in the axilla, and keeping the patient under close surveillance while the temperature was being taken. The woman finally confessed to the imposition she had practised, and said she had learned the trick from a woman in a hospital in another town.

The weather is pretty cold in Helsingborg, and an industry that will insure a warm shelter and plenty to eat, even though it may be hospital fare, is likely to become popular. But then it is overworked and the game is spoiled. Another refutation of the theory that competition is the life of trade.

THE INFLUENZA.

The influenza is a very peculiar disorder, and no one can make positive predictions as to its future developments. We are much inclined, however, to discredit the sensational prophecies which have been made in the newspapers regarding another epidemic. The past history of influenza shows that it does not repeat its severe

visitations of any given locality for at least eight or ten years. The severe epidemics of London, for example, all occurred in the single seasons of 1831–32, 1837, 1847–48.

The diagnosis of influenza is not always easy, and there is really at date of writing no evidence that the disease is as yet alarmingly prevalent in this city. Such presence is usually shown by an increased death-rate, especially from pneumonias; but reports from hospitals and the Health Board do not show such increase.

We trust that there will be no undue alarm excited over the very doubtful prospect of an epidemic.

INSANITY AND GENIUS.

A good deal of comment has been excited by the publication in English of Professor Lombroso's work on "Insanity and Genius." It is a work in which the author claims that genius is the evidence of a degenerative taint, and is, in fact, an "epileptoid degenerative psychosis." We trust that our readers will not be made to feel a sense of apprehension concerning their own mental soundness by Professor Lombroso's thesis. It is one that has been worked at before by Moreau de Tours and a good many others, and neither the world in general nor the medical profession in particular has been seriously impressed by it. Men of genius have not, as a rule, been mad, except with an insanity of a scientific and scholastic kind, such as the world really needs more of. The eccentricities, monomanias, and emotional exaltations of genius have been incidental, and were not the basis of their character and temperament. Insanity is essentially a non productive condition; no insane man has ever made a great discovery and originated great thoughts, or, by his own laborious efforts, changed the tide of human events. Insanity is a condition in which the power of adjusting one's self and one's conduct to the environment is lost. Surely there is no loss of this kind shown in the work or conduct of men of genius. Contemporaneous science has dealt somewhat kindly with Lombroso for the valuable work he has done and the new fields of study he has opened. But when he makes out Newton and Luther insane, and Christ a paranoiac, one must think that the Professor himself has neither sanity nor genius.

AN INDICTMENT OF THE TRAINING-SCHOOL FOR NURSES.

We called attention a short time ago to the fact that the work of the trained nurse was a hard one, and her average health perhaps below the normal.

We were hardly prepared, however, to find following somewhat in this line a most savage onslaught on training-schools in general. Such an attack has been made by Mr. Peck, a Western clergyman, whose daughter died of phthisis, contracted, as he believes, from patients whom she was attending. The clergyman in question heads his article, published in the Cleveland *Leader*, "The Massacre of Nurses," and begins with a quotation from Rudyard Kipling:

"She had hoped to befriend misery, to bring help and healing to pain from the first days of her apprenticeship. What she actually was set to do was to scald babies' milk-cans."

"Through all ran the bad food, the scanty sleep, the insufficient hours of recreation, the cruelly long hours assigned for work, the nervous strain of supporting life from the merely physical point of view."

He adds, among other things:

"This training in some hospitals means polishing the faucets and dusting the furniture, and low menial duties entirely apart from any sensible training. . . . Some of these hospitals [of New York] are humanely conducted, while others have the name of building up a reputation on the blood of young women in ostensible training for nurses. The New York Hospital has an excellent name, while other hospitals of that great metropolis are mainly known as death-traps. They are far too willing to kill the noble nurse in order to save the often ignoble patient. To kill the nurse means little, to save the patient means medical reputation, and constantly they sacrifice our daughters to save their dollars. The institution which slaughtered my daughter has a reputation for doing the deadliest kind of work. This is the calm, cool testimony of those who wish its welfare."

Mr. Peck propounds also these questions:

"Do you know that more than half the trained nurses die of consumption? Do you know that from one to five years is quite likely to end your life with some vital disease if you choose this occupation? Do you know that if you pass through the two years of training you are likely to be a physical wreck afterward, and your life a burden to yourself and friends?"

A good deal more of the same kind is written, but the above is sufficient to show the general tenor of Mr. Peck's argument and the excited state of his emotions.

A great deal can be allowed to a person who has been so unhappily bereaved; and some measure of truth undoubtedly exists in the gentleman's charges. But the article as a whole does a gross injustice to our training-schools and hospitals, and to the philanthropic people who support them.

In place of reckless and sweeping statements regarding the death-rate and sick-rate among nurses, Mr. Peck should have investigated the matter carefully and given the actual facts. The assertion that "more than half of trained nurses die of consumption" is grossly untrue and calculated to cause much unnecessary alarm. The Rudyard Kipling quotation is a half-truth strikingly put. Young women who enter training-schools cannot at first be put in full charge of critical cases, and if they think that the work of a trained nurse begins and ends with sympathetic coddling of hysterical invalidism the blame is theirs. The careful cleaning of a baby's bottle is a great deal more important to the baby than hugs and kisses and soft lullabies.

The young woman who first enters a training-school has many illusions promptly dispelled. But she is not a prisoner, and if the work is disappointing she can leave it. Furthermore, she soon, if at all intelligent, learns the dangers of her calling and the strain it puts upon her.

But the nurse, as a rule, gets fond of her work, despite the bottle-washing and bad food and long hours. She will not leave it, she often refuses advice to take rest, and

neglects the precautions which might save her from sickness.

This, we believe, explains much of the sickness among nurses, and we may be permitted to wonder if the sad death of Mr. Peck's daughter was not in part due to some such cause.

THE PAN-AMERICAN MEDICAL CONGRESS AND OUR BRAZILIAN CONFRÈRES.

In speaking recently in these columns of the permanent organization of the Pan-American Medical Congress, we referred to the omission of Portuguese from the languages in which the preliminary publications are to be printed. It seemed to us to be a mistake, and we feared that it might be construed as a slight by the Brazilians. We are glad to learn, however, that the Executive Committee of the Board of Trustees of the Congress has decided to retain Portuguese, out of consideration for the large number of distinguished physicians in South America who speak this tongue, and as a mark of recognition of the cordial co-operation which the committee is receiving from the physicians of our sister republic of Brazil. This is as it should be, and we rejoice to find that in our criticism of the work of the organizers we were misled by the published report of the proceedings. This question of language may seem a small matter, but it is one that directly touches the passion of patriotism, and a mistake at the outset might mar the whole plan of organization.

SUICIDES IN INDIANA.

Dr. W. B. Clarke, of Indianapolis, being in a statistical frame of mind during the past year, has kept a record of the suicides and attempted suicides in his State for the twelve months ending with October, 1891. The results were published in the Indianapolis *News* and present a curious study.

The first thought that strikes one is that Indiana must be a rather undesirable place of residence if so many people prefer the terrors of the unknown to the evils of a longer stay where they were. During the twelve months ending October 30, 1891, no less than 426 men, women, or children laid violent hands upon themselves, 282 of them with success. These figures are certainly much below rather than above the facts, for Dr. Clarke says that he was away several times during the year when no record was made, and furthermore the statistics are based solely on newspaper reports, which of course are far from embracing all the cases, at least of attempted suicide, that actually occurred.

The youngest self-destroyer was a lad of twelve years, and the oldest was a man of ninety-two. After living on for such a length of time one would think the poor man might have had patience to wait the few years, or perhaps only months, that yet remained to him. Shooting was the favorite mode of suicide, leading the list with 84, and next to it came poisoning by morphine with 61, and then followed hanging with 53. Hanging was the favorite mode with farmers, probably for the reason that it was difficult to procure poison at the time that the suicidal impulse was acting. Seventeen followed Anna Karenina's example by throwing themselves before a train, one of them evidently in despair of succeeding in any other way, as he had made four previous attempts and failed. "Rough on Rats" figures, as usual, quite prominently, 13 cases from this cause being included in the list.

The greatest number of cases in any one month (48) occurred in July, next to which come December and January with 40 each; October had but 15.

The compiler of the statistics calls for legislation to restrict the sale of poisons—a useful measure in preventing accidental death, but of little avail in preventing suicide.

NOT AN EXCEPTIONAL CASE.

The following advertisement appeared in the physicians' personal column of the Medical Record for December 12th:

"A Young Physician, practising in this city for nearly two years, and earning less than one-quarter of his expenses, desires to know of an opening where at least, he can make a living."

It hardly seems necessary to comment on this, for it tells its own tale. How many men who read it will not feel a sympathetic chord touched in the memory of their own past, of the early years of struggle for a living and of bitter discouragement if not of actual want? It is indeed a mournful experience and one which few would have the courage to face were they able to realize its tortures beforehand. It is hard enough to wait for the practice to come, even when this waiting is free from any anxiety as to the means of support, but for a poor man who must support himself and may be, too, a wife and several little ones, it is bitter indeed. What with the overcrowding of the profession here and in all large cities, and the relentless and unscrupulous competition of the thousand and one dispensaries, infirmaries, clinics, and hospitals of every sort and kind, a poor man has little show and he had better not study medicine, not, at least, unless he has more than ordinary push and go and business tact—and possibly also ability.

But our young friend whose complaint and appeal we have quoted is too easily discouraged. If he has made anywhere near one-quarter of his expenses in the first two years of practice he has nothing to complain of, for he is better off, we venture to affirm, then the majority of young men of his own age, professionally. Anyone, we may safely say, who is able to cover his legitimate living expenses by the fees received from patients before the completion of his fifth year of practice, is doing as well as he can expect. Of course, there are many who do better than this—men who are helped along by older professional friends, who have a dispensary appointment and can work up a practice from that, and some few who possess the qualifications above mentioned. But they are not the majority, and there are men of much older medical life here in New York who are not making their salt.

So we say that this young physician is too easily discouraged. He ought not to have expected to jump at once into a paying practice. If he has the right stuff in him, can wait long enough, and neglects no opportunity to get and keep a patient, he may be able to pay his way at the end of another two years. If he cannot wait so long, he had better do something else.

But whatever you do, young man, don't lose heart. You will never gain anything by waiting, and self-confidence and a belief in ultimate success will do much in bringing success. Peg away, look outside for other work that you can do while waiting for what you have chosen as your life-work. But be sure, first, that you are fitted for the life of a physician and that your heart is in your profession, for without these essential conditions it is hardly worth while to struggle on, and you had better turn your hand to something else. There is, perhaps, no occupation where a love for the work in itself is so necessary to success as in medicine. It is not an easy path to walk at the best, but it becomes almost impossible when a distaste for practice clogs the feet.

THE SELF-PURIFICATION OF RIVERS.

The question of the purity of water-supply presented itself to the inhabitants of this city in a very disagreeable way last summer, for while the contamination was at no time sufficient to cause fears for the actual present, it was suggestive and alarming in the way of showing what it might in time become. But for many other cities and towns whose water-supply is derived from rivers which receive all the sewage of towns above, the subject is one of ever-present interest.

At a meeting of one of the sections of the International Congress of Hygiene and Demography, in London, last August, Dr. Percy Frankland read a paper on the present state of our knowledge concerning the self-purification of rivers which was of a character to cause considerable uneasiness to dwellers on the banks of such long rivers as the Ohio, flowing past many large cities and receiving all their refuse, yet furnishing the only water-supply to these same towns and others below them. The writer contended that there was no such thing as the "self-purification of a river," and that the evidence brought forward to sustain that theory was fallacious and wholly inadequate to justify the drinking of water from a river which had received sewage contamination at any point nearer its source.

But now we have the opinion of Professor von Pettenkofer to the contrary. He has been examining the water of the Isar River, which flows through the city of Munich, with a population of between 250,000 and 300,000, and receives all its sewage. He made careful analyses of the water at different points, and found that all trace of pollution had entirely disappeared five miles below the city. Some workers in this field have held that the foreign matter was simply deposited as sediment and liable to be mixed with the water of the river at every freshet, but Dr. von Pettenkofer maintains that the real agent at work in purifying a river is the oxygen of the air which is absorbed by or dissolved in the water.

The results of von Pettenkofer's investigations are in line with the more popular theory, and are more quieting to the minds of dwellers in cities by the rivers; but it would be safer to follow Dr. Frankland's advice and seek a water supply from some pure source that can be proved to be above suspicion.

Trional is said by Schultze to be a good hypnotic in doses of one to three grammes.

News of the Week.

Death as the Result of Violating the Code of Ethics.—A gentleman of New Orleans, responding to the invitation of a medical student to witness an operation at a clinic, was suddenly stricken with paralysis on taking his seat in the amphitheatre, and died shortly afterward.

Precautions Against Small-pox.—Assistant Secretary Nettleton has directed that a sanitary inspector be stationed at Rouse's Point, N. Y., during the prevalence of small-pox in Canada, to prevent the introduction and spread of that disease in the United States. The Collector of Customs at Plattsburgh recommended this action because of the large number of cases of small-pox of a malignant type in the vicinity of Montreal and Quebec, where the death-rate is said to be alarmingly large.

Faith without Works.—A clergyman of Wilkesbarre, Pa., awoke recently at night, said he was suffocating as the result of swallowing a set of false teeth. The family was summoned and the parting farewells given. While these significant and impressive ceremonies were in progress the truant teeth were discovered in a bureau drawer, whereupon the farewells were indefinitely postponed and the patient rapidly recovered.

A Suit against the New York Hospital.—Fifty thousand dollars damages has been brought against the New York Hospital in a suit for malpractice, the claim being that by tight bandaging of a fractured leg mortification of the extremity ensued, resulting in amputation.

A Belated Inscription.—Dom Pedro, ex-emperor of Brazil, has recently presented three medals to Doctors Simmola, Charcot, and Count de Mott-Maica. They have on one side the portrait of Dom Pedro, while on the other is the inscription: "Presented to Dr. —— by the Brazilian people out of gratitude for saving the precious life of their paternal emperor." While the medals were being prepared his grateful subjects drove their "paternal emperor" from the country. They were finished a few weeks ago, and were forwarded to the ex emperor, who had ordered them, arriving on the day of his funeral. *Sic transit*, etc.

Magnetic Girls.—A correspondent asks us how and when the tricks of the "Georgia Magnet" were exposed. The only magnetic girl who ventured to give exhibitions in this city was a Miss Hurst. It was abundantly shown at the time that her apparent feats of strength were due to sudden quick and dexterous movements on the lady's part. The subjects operated upon were taken off their guard, and were really made to help in the apparent exhibitions of strength.

Something One Gets in Germany.—There are a great many different inducements for making a trip to Europe. *The College and Clinical Record* states that Professor Parvin, while in Germany, last summer, secured a large number of female sexual organs for use on his obstetrical model. There was no duty paid, and we trust it will not be necessary to apply the principles of protection to this singular industry.

The Medical Department of the Sioux City Normal University has been abandoned.

An Italian Translation of Dr. Lewis A. Sayre's Work on "Spondylitis and Rotary Lateral Curvature," and also

of the paper on the "Treatment of Rotary Lateral Curvature," by Dr. Reginald H. Sayre, has recently been published by Professor Filippo Scalzi, of the University of Rome. It is very neatly printed, with all the illustrations of the American original.

Dr. Robert T. Wilson, of Baltimore, has been elected Visiting Physician to the Home for Incurables of that city.

The Health of the American Hog.—German inspectors have found that two and a half per cent. of American hogs are trichinous; but they also find the parasites dead, and consequently harmless.

"The Dying Prophet."—An extraordinary person, who goes by this name, is creating intense religious excitement in Russia. He dies every Saturday night and comes to life Monday morning. In the interim he has intercourse with the recording angel, and learns the secrets of human lives. The accounts state that he was born in the Caucasus, where he now lives. He is yet a young man, of humble rank in life, and of only ordinary education. Since childhood he has been bedridden and utterly helpless. For years he lay in his humble cottage, in the outskirts of Tiflis, with nothing to distinguish him from any common invalid. But a few months ago a curious change was observed. In brief, he died, to all appearances. His friends believed him dead. The doctors declared him dead. According to all ordinary tests, he was certainly dead. That was on Saturday. They prepared his body for burial, and the corpse lay in its coffin until Monday, when the funeral was to take place. At the very hour set for the obsequies, however, the young man suddenly returned to life. Ever since, the same event has occurred every week.

Chicago has got a Temperance Hospital, and the hospital has got $100,000. This with the World's Fair ought to make Chicago very contented. It will be a relief also to those from eastern lands of steady habits, to know that when they visit Chicago they can go to a temperance hospital if ill. Chicago is getting almost everything. Some day, we trust, it will have a medical journal.

Dr. W. F. Peck died in Chicago, December 13th. He was the founder of the medical department of the Iowa State University, was Dean of the Faculty, and has for twenty years held the chair of surgery in the institution.

Dr. M. L. Ruth, of the United States Navy, died in Washington on December 14th. Dr. Ruth was born in Pennsylvania, and was appointed an assistant surgeon in the navy on April 21, 1868. After serving on the North Atlantic Station and in Europe, he was appointed to the Bureau of Medicine in 1874. From 1877 to 1880 he was on special service, after which he became full surgeon, and served for five years on the Asiatic station in the Essex. Since 1885 he has been on duty in Washington, where he was a very prominent and popular figure in social circles.

The Woman's College of Baltimore, a well-known institution under the care of the Methodist Church, is said to have decided to establish a preliminary medical course, preparatory to the medical course for women which is some day to be opened in connection with the Johns Hopkins Hospital and Medical School.

Advertising in Medical Journals.—The *Journal of the American Medical Association* prints the card of a physician, and in addition gives a generous and flattering editorial "reading-notice" of its patron.

The "Dean" of the Medical Faculty of Berlin is Dr. Steinthal, who is ninety-three years of age, and has been in practice for seventy years.

An Anglo-Imperial Medical Congress.—It is proposed to hold a medical congress made up of delegates from Great Britain, Ireland, and the English colonies.

The Congress of American Physicians.—Some of our contemporaries are worried unnecessarily, we think, over the following editorial item from the *American Practitioner and News*. Dr. Yandell says: "The Congress is clearly on a solid working basis, and being so constructed as to harmonize all the heterogeneities of the many diverse societies of the land, will soon supplant the American Medical Association as the representative of American medicine. The latter, we fear, is too much handicapped by politics and local prejudice to distance its young competitor in any future race."

Dr. Walter Rae, of Jersey City, N. J., died suddenly of apoplexy on December 10th. Dr. Rae was born in Scotland about forty-five years ago.

Dr. Frank Donaldson, Senior, of Baltimore, Md., died on December 9th, aged sixty-nine. Dr. Donaldson was born in Baltimore, and took his degree at the University of Maryland. For forty years he was connected with that institution. He was an active member of many medical associations, and a contributor to the medical journals. He was the author of several valuable works on lung diseases, and was particularly known for his work in this line and in diseases of the throat.

Dr. David S. Smith, of Irvington, N. J., died at his home, in that township, on December 8th, at the age of sixty.

Dr. Hugh H. Abernethy died at his home, in Jersey City, on December 10th. Eighty-three years ago Dr. Abernethy was born in Bucks County, Penn. In 1830 he was graduated from the University of Pennsylvania and began the practice of medicine. For fifty years Dr. Abernethy was recognized as a successful surgeon and physician.

A Novel Offence against a Physician.—A recent number of *Vratch* quotes a statement to the effect that a St. Petersburg physician was about to prosecute a man who had caused one of the physician's prescriptions for his deceased wife to be posted over her grave, in order to call public attention to his belief that the medicine had been the cause of her death.—*New York Medical Journal.*

No Fee, No Sutures.—*The Medical Standard*, commenting on the case of Dr. L. W. Whitney (who cut the stitches of a wound he had sewed up when a promise of immediate payment was not fulfilled), hoped that this legally justifiable course would not be imitated. This hope was disappointed. Dr. Cragin, county physician of Cumberland, Md., sewed up the wound of a patient who called on him under the belief that gratuitous treatment was part of the duties of a county physician in charge of a jail, almshouse, and insane hospital. Dr. Cragin's fee was refused, whereupon he cut the stitches.

Compressed Medicine to be Used Hereafter in the Army and Navy.—The army medical service is interested in a contract which was awarded at the War Department for a new system of carrying medical and surgical supplies for an army. Ever since the last Sioux campaign there has been a growing demand for a plan by which supplies needed by the surgeons could be placed in a more compact form than liquid, and carried with greater safety and economy. The result of the award is believed to be as near perfection as possible. In a small, light wooden chest, 23 inches long, 14½ inches wide, and 17¾ inches high, are sixty square bottles, containing as many different kinds of medicine, but in compressed tablet form, none of them being larger than an ordinary peppermint lozenge. One of these lozenges or tablets contains all the necessary ingredients of a liniment, and when dissolved in an ounce of distilled water its healing properties are the same as if it was in liquid shape and in a big glass jar. Some idea may be formed of the perfection to which the art of compression has been brought, by the fact that if the contents of this small brass-bound chest were liquefied and in their customary jars and bottles, they would occupy nearly one-half of the space of a regular freight-car. After all, however, fluid extracts and powders take up less space than compressed tablets.

Apoplexy in Rome.—The "Dea Febris" was invoked in the City of the Seven Hills to avert the local fever, and, in later times, a special saint is worshipped by the devout to save them from death by apoplexy. Statistics might be adduced to show that apoplectic seizure—or, at any rate, cerebral hemorrhage—is exceptionally frequent as a "mode of dying" in Rome, the heavy atmosphere, charged (in the Campagna particularly) with malaria, and the remarkable stillness of the air, due to absence of winds, being eminently favorable to "determination of blood to the head." The saint whose intercession is implored by subjects of an "apoplectic habit," hereditary or acquired, is, curiously enough, St. Andrew. Now, as that apostle was, according to ecclesiastical tradition, crucified head downward, at his own request (as he deemed himself unworthy to win the martyr's crown in the position in which his Divine Master died on the cross), we can readily understand how he should have been selected by the faithful as the typical example of death by congestion or stasis of the cerebral circulation, and how in the saintly calendar he should be especially invoked to protect his votaries from dying by a similar cause.—*Lancet.*

Collapse of Another Cancer Cure.—A few months ago Professor Adamkiewicz announced that by means of some experiments he had been able to arrive at a certain method for curing cancer. The excitement which this announcement made in Vienna was such that the Minister of Education was induced to invite the Professor to come to the Austrian metropolis for the purpose of testing his new treatment in one of the state hospitals. In a ward under the charge of Professor Billroth, Adamkiewicz was permitted to experiment upon a patient who was believed to be affected with epithelioma of the upper and lower lids of the right eye. The history showed that the disease was rapidly spreading, and, under the circumstances, therefore, the case seemed a most suitable one for testing the value of the new treatment. On October 25th the Professor took the patient in hand, the result being that on November 12th the sufferer was discharged from the hospital—cured. In other words, after eighteen days' treatment an epithelioma of the upper and lower lids was pronounced by Adamkiewicz to have perfectly cicatrized over. Professor Billroth examined the case and asserts that the patient was not cured. Professor Albert adds that other experiments of Adamkiewicz in his wards were unsuccessful.

The Brain of the Dynamiter who was blown to pieces in trying to coerce two millions out of Russell Sage has been examined, and declared to show evidences of insanity. The weight of the entire brain was 1,210 grammes, which is about two hundred grammes or six ounces below the average. The cerebellum weighed 154 grammes. The dura mater had a ballooned appearance, as if blown up, but was normal. The pia was healthy. Over the hemispheres, mostly on the left, in various sulci, and at the base, there were numerous extravasations of blood, evidently of recent origin, and due to the explosion. These were on the surface and beneath the pia mater. There were no adhesions of the pia mater to the cerebrum. There were some slight lacerations of the brain-substance, also evidently recent and due to the dynamite. The left ascending parietal convolution, especially in its upper half, and the left first temporal convolution, especially in its anterior half, were greatly atrophied. The gray matter of this left ascending parietal convolution was five millimetres in depth, and that of the left first temporal four millimetres, while the gray matter of the left ascending frontal convolution was ten millimetres in depth, and that of the other convolutions varied from ten to seven millimetres. The left crus cerebri was four millimetres smaller than the right, and the left half of the pons was four millimetres smaller than the right. These abnormalities were all that were visible to the naked eye; the frontal, parietal, occipital, sphenoidal, and temporal lobes of the cerebrum, the corpus callosum, the basal ganglia, the crura, the pons, the medulla oblongata, the spinal cord (only its ultra cranial end), and the cerebellum having been carefully examined. But although not positively diseased, other than as described, the convolutions of the cerebrum were undersized, and the sulci were shallow.

Influenza and Neuroses.—The following, according to Dr. George H. Savage, are some of the unpleasant things that influenza can do: Influenza, like other fevers, may set up psychopathy. Insanity may come on at various periods of the disease. It may start any form of insanity. No specific symptoms result from influenza. The rôle of the influenza varies in the production of the insanity. It may be the predisposing or the exciting cause. In all cases there is some acquired or inherited predisposition. The insanity follows from altered brain-nutrition, possibly toxic. Onset of insanity often sudden and bearing no relationship to the severity of the influenza. The curability depends on the general rather than special conditions. The insane are less disposed to take it than the sane. Rarely it has cured psychoses. The insane may have mental remission during the influenza. There is no special indication in the treatment. Influenza may lead to crimes and medico-legal issues.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Adjourned Annual and Stated Meetings, November 23, 1891.

DR. O. B. DOUGLAS, THEN DR. G. H. FOX, IN THE CHAIR.

Report of the Committee on Hygiene (DR. A. JACOBI, Chairman).—The adjourned annual meeting being called to order by the outgoing president, Dr. Douglas, the Society listened to the above report. Dr. Jacobi requested Dr. H. D. Chapin to read that part of the report relating to the condition of the public schools. DR. CHAPIN said that they had visited others of the public schools than those visited last year, besides again visiting the latter to learn whether evils previously pointed out had been remedied. The unhygienic condition, relating to ill ventilation, want of sufficient light, overcrowding, etc., had not been remedied in those visited last year. The worst state of things was found in the primary, not in the grammar, schools. Inquiring into why the evils had not been corrected, he said it was due to divided responsibility between Boards of Trustees, the Board of Education, and the Board of Apportionment. The Board of Trustees was a local board, and sometimes failed to ask the Board of Education for money to make repairs or an improvement, preferring to let a bullding get into as bad a condition as possible in order that the time might be hastened when they could get an appropriation for a new one. The Board of Education was to blame for expending a disproportionate amount of the school money on what might be called the ornamental grades, leaving the primaries to suffer. The Board of Apportionment failed to grant sufficient money for the schools in general. Dr. Chapin thought a remedy would be forthcoming if the Board of Health were given the power not only of condemning a building when in an unhygienic condition, but also of peremptorily closing the school if the evil were not corrected. If this were done in one or two instances the press would soon arouse such a sentiment that complaints would not long go unheeded.

DR. A. JACOBI then offered the following resolution, which was adopted unanimously: Resolved, that the Board of Health and the Health Department be requested to use both its actual authority and moral influence to secure for the school children a sufficient amount of air, light, and accommodation, and to protect them from the dangers to their health unavoidable in the present condition of the majority of the common schools.

Need of More Hospitals for Contagious Diseases.—DR. JACOBI read the remainder of the report, which dwelt on the necessity for at least four more hospitals like the Willard Parker, located in different parts of the city so as to be accessible to all, where persons could be taken when stricken with scarlet fever or diphtheria. There was also urgent need for temporary retreats for healthy members of families in which any of the contagious diseases prevailed.

There was especial need for a hospital where strangers visiting the city, or here on business, could go if taken with small-pox, diphtheria, or scarlet fever.

A resolution was passed, urging an increase of the special hospitals for diphtheria and scarlet fever, and expressing the conviction of the Society that there is no better protection against the multiplication of contagious diseases throughout the city than by providing temporary homes for the numerous children gathered around the cases of pestilence from which there is no remedy except in flight.

DR. DANIEL LEWIS read a report, setting forth the financial prosperity of the Medical Directory for the county of New York.

DR. DOUGLAS, before introducing his successor in the office of president, made some remarks on the prosperous state of the Society, and said in no previous year had so many new members been admitted, and at no time before had there been so much money in the treasury. He hoped the Society would in time have a sufficient sum to secure a permanent home.

DR. GEORGE HENRY FOX, President-elect, then called the stated meeting to order, and appointed the following committees: On *Hygiene*, W. A. Ewing, Chairman, George H. Bosley, S. H. Dessau, Mary Putnam-Jacobi, Robert T. Morris; on *Ethics*, A. B. Ball, Chairman, Everett Herrick, Frank W. Jackson, Laurence Johnson, W. H. Katzenbach; on *Prize Essays*, E. B. Bronson, Chairman, Samuel Lloyd, Beverley Robinson; *Auditing Committee*, William Stevens, Chairman, George T. Jackson.

Clinical Remarks on Pulmonary Œdema.—DR. A. ALEXANDER SMITH read the paper (see p. 730).

DR. J. WEST ROOSEVELT agreed with the author that œdema of the lungs could not be produced mechanically. It was probably brought about by the influence of the nervous system. Against the mechanical theory was the fact that it was perfectly possible for the heart to be working well, yet pulmonary œdema take place. Apparently two factors were necessary to produce it, the one constant, the other might be variable. The constant factor was a changed condition in the sympathetic nervous system. The variable one might consist in disease of the heart, of the lungs, of the kidneys, etc. As to treatment, personally he had not been as unfortunate in the use of dry cups as the author. He was very glad to hear strychnia endorsed so warmly. He had made use of it in much larger doses than $\frac{1}{10}$ gr. He could recall one case in Bellevue Hospital where they gave $\frac{1}{30}$ gr. hypodermically every half-hour until four injections had been made, and afterward $\frac{1}{60}$ gr., according to the condition of the pulse. The man recovered from his œdema and pneumonia. He also thought it would be necessary in many cases to give nitro-glycerine in larger doses than $\frac{1}{100}$ gr., if one would obtain much effect. He had given as much as $\frac{1}{25}$ gr., diminishing the amount according as the pulse showed the effect which he sought. The value of morphine was also unquestionable.

DR. F. P. KINNICUTT corroborated what Dr. Roosevelt had said regarding the value and size of the dose of strychnia and nitro-glycerine. He had for some years been accustomed to treating certain conditions of the kidneys with large doses of nitro-glycerine, giving, say $\frac{1}{60}$ to $\frac{1}{100}$ gr. every fifteen to twenty minutes. The quantity might be governed by the patient's consciousness of the effect; unless it produced flushing of the face and an uncomfortable feeling in the head the right dose had not been exceeded. This amount could be continued almost indefinitely without harm. Its effects were very evanescent, and he doubted whether if it were repeated only at intervals of an hour or two hours its effects on the blood-vessels could be kept up. His experience with strychnia had also been like that of Dr. Roosevelt.

DR. ANDREW H. SMITH corroborated what had been said regarding the influence of the nervous system in causing œdema of the lungs; also as to the evanescent influence of nitro-glycerine, which he believed was eliminated in forty-five minutes. Where it was desired to keep up the action for some time he preferred some other nitrite, as the nitrite of sodium. Oxygen had been useful in some cases in his hands, and he could not understand why it should produce a sense of dyspnœa, unless in the sense that a strong current of air would do so. He was glad the author had omitted mention of digitalis, which, perhaps, was often given in pulmonary obstruction, but was sure to do harm. Digitalis would cause the arteries to empty into the veins, whereas in these cases it was desired to empty the veins into the arteries.

DR. RICHARD VAN SANTVOORD had in several instances observed the effect of nitro-glycerine by the sphyg-

mographic tracings of the pulse. The maximum effect was reached in about ten minutes, and it passed off very rapidly, which showed the necessity for frequent doses in very acute cases.

Dr. A. A Smith said that nitro-glycerine given in doses of one to twenty-five grains every half-hour would after three or four doses cease to produce the characteristic effect. The same thing would be observed if one to one hundred grains were given frequently, say every fifteen minutes. He had, therefore, spoken advisedly when he said he would give it in these cases only once in two hours, then as an aid to the other drugs as well as for its own effects.

The Simple Incision for Perityphlitic Abscess.—Dr. Charles McBurney read a paper with this title. The simple incision introduced by Willard Parker had undoubtedly proven useful in its day, being superior to methods previously in vogue. The paper, however, showed that with our further knowledge of perityphlitic abscesses it was unsafe to delay an operation with the hope that the abscess might reach a point in the inguinal region where it could be opened by simple incision. The position of the vermiform appendix, where it was now known the inflammation had its origin, the frequency with which the abscess failed to establish connections between the peritoneum and the external walls, the danger of rupture into the gut, into the peritoneum, etc., were clearly shown to make it dangerous to delay. Out of many illustrative cases which had come under his observation, he related the histories of about half a dozen. Some showed that where one might suppose the simple incision was practicable and would prove easy, in reality unlooked for dangers were encountered, the free peritoneum had to be entered, etc.

Dr. Joseph D. Bryant said that from an anatomical standpoint, and also from clinical observation, he thought the simple incision objectionable. It limited the opportunity for observing the seat of the disease; it limited the opportunity for drainage; it offered no direct way for removal of the disease itself. As bearing on the first point, the seat of the disease, he submitted an analysis of a hundred cases, autopsies in which Dr. Briggs, at his request, had kindly examined the vermiform appendix—1, As to its origin; 2, its size; 3, its length; 4, its situation; 5, its direction; 6, its contents; and some other facts which he did not then remember. In the 100 cases the most frequent situation of the appendix with reference to the cæcum was as follows: directly behind the cæcum, 20; behind the cæcum and internally, 2, extending in one of these up to the liver; behind the cæcum and running upward, 4. Behind the cæcum meant hanging down behind the cæcum or curled up behind it. Of the 100 cases it was freely movable in any direction in 21. In these 21 cases it extended in 10 into the pelvis, in 1 it extended into the hollow of the sacrum. It was very evident that in cases where the appendix extended into the pelvis, simple incision would offer very little opportunity for observation and for drainage. Eight of the 100 extended to the brim of the pelvis; 79 were not free, that is, they had a mesentery, long or short.

As to the contents of the vermiform appendix in the 100 cases, 70 of the patients were known to be males, and in 30 of the 70 cases the appendix contained fecal matter. In 52 of the 100 cases the fecal matter was hard; in 13 it was soft; in 12 its consistency was not stated; 6 contained mucus; 4 contained mucus and fæces; 2 contained mucus and pus; 1 contained fæces and pus; 1 contained mucus and gas; 2 were impervious; and only 21 were empty. Of the females, in only 12 were the contents of the appendix examined; fecal matter existed in 3, hard in 2 and soft in 1; 1 contained gas and mucus; in 7 it was empty, that is, there was a larger per cent. empty in females than in males, which corresponded to the clinical fact that disease existed oftener in males than in females. In not one of the 100 cases was a grape-seed or foreign body found in the appendix. In 6 cases the appendix was extra-peritoneal, showing that it was possible for perforation to be subperitoneal. With regard to treatment, he subscribed to what Dr. McBurney had said.

Dr. A. G. Gerster said he supposed the paper was directed against the improper application of the simple incision in perityphlitic abscess. When, as sometimes happened, the abscess had reached near the surface, causing inflammation and thickening of the tissues above and shutting off the general peritoneal cavity, there could be no doubt that incision and drainage was proper and a simple procedure. On the other hand, there could be no doubt that a large number of cases would not, if allowed to go on, end in that way and permit of such simple treatment.

The more intimate anatomical character of perityphlitic abscess was not known before the work of McBurney, Sands, Weir, and others. In not all cases did the walls of the abscess enter into close relation with the parietal peritoneum, and consequently an operation must be done with much skill in order to avoid infecting the peritoneum and setting up sepsis. But by surrounding the abscess with gauze and making a small puncture, so that the pus should escape very gradually, one could operate with much greater safety, because not soiling the peritoneum, than he could under old methods. He mentioned the fact that the feel might lead one to suppose inflammatory adhesions to the parietal peritoneum and abdominal walls had taken place, and so be led to puncture to determine the presence of pus, and much to his chagrin find no such adhesions had formed, and that his puncture had resulted in infecting the peritoneum. With most surgeons the aspirator was something which had been relegated to "limbo."

Dr. R. F. Weir thought the author, speaking as he supposed of encysted perityphlitic abscess, had justly taken the ground that an incision should not be postponed. The simple operation should not be delayed since it was liable to be complicated and attended with unexpected dangers. Septic processes were liable to develop which might be obviated by an immediate operation, especially where the abscess was behind the cæcum. If allowed to go on, the abscess became large, and required greater skill to drain and otherwise treat safely.

Should the Appendix be Searched for?—Regarding the question whether the appendix should be sought, he said it was desirable to remove it when it came readily into view, but time should not be taken in looking for it. It was not very likely to do further harm if not removed; usually it had disappeared by gangrene, or by sloughing, was closed at the cæcum.

Dr. L. A. Stimson thought the great objection to the simple incision was in waiting for the time when it could be practised, for meanwhile the patient's condition might become such that no course would then save him. The statement had been made that in a large proportion of cases perityphlitis was a simple disease, yet within a few months he had seen nine cases, and in three of them the patients reached a condition in which they were in immediate danger of death while waiting for a simple incision; that was thirty-three per cent.

Dr. McBurney endorsing the remarks of Dr. Gerster in opposition to the use of the aspirator, said that he would not advise that much time be spent in looking for the appendix, but yet to leave it was not without some danger of subsequent trouble.

The Latest Substitute for the Compound Pill is a gelatine capsule with various compartments, each one containing one of the ingredients in powder or extract, uncombined.

A Variegated Complexion.—The case is reported by Dr. McHardy, of England, of a boy, the upper part of whose body was deeply jaundiced while the skin below the level of the umbilicus had the pink hue of health.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

DR. BURDON SANDERSON'S CROONIAN LECTURES ON THE PROGRESS OF DISCOVERY RELATING TO THE ORIGIN AND NATURE OF INFECTIOUS DISEASES—THE ASSOCIATION OF SANGUINOLENT PLEURAL EFFUSION WITH ABDOMINAL DISEASE.

LONDON, November 28, 1891.

HAVING endeavored to show that the proximate cause of inflammation is always chemical, Dr. Burdon Sanderson proceeded to discuss Metchnikoff's theory of phagocytosis and what has been termed the "chimiotaxis" of leucocytes. He urged that the facts of chimiotaxis did not lend any support to the theory of Metchnikoff, that the leucocytes were actuated by an almost conscious discrimination of what is advantageous to the organism. Dr. Sanderson remarked that while we are now able to understand better what Sir John Simon taught thirty years ago, viz., that there is an antagonism between inflammation and contagion, between leucocytes and viruses of all kinds, there is no reason for attributing this to the maintenance of a mysterious relation between the leucocyte and the organism with which it is no longer in structural continuity.

The lecturer discussed in succession the subjects of attenuation, immunity, and that of specificity. He observed that the term "attenuation" had replaced the old word "mitigation," and there is no objection to it provided that we remember that what is thus designated is not what Pasteur originally meant by attenuation. For "insusceptibility" we had also taken to the use of the new word "immunity," which was inconvenient, because the states to which we have most frequently to refer are neither states of immunity nor of the contrary, but somewhere between the two.

In considering the etiology of specific infectious diseases, Dr. Sanderson took as examples tuberculosis, typhoid fever, pneumonia, tetanus, and diphtheria. Having discussed these several diseases in some detail, the lecturer said the question in respect to each was, How does the supposed cause produce the effect attributed to it? The answers had been found to be as different as the diseases. Some morbific agents acted by virtue of their endowments as living organisms, others chiefly by virtue of the "toxines" which they produced. Thus in splenic fever and (in a different sense) in tuberculosis the morbific action was pre-eminently biotic, in diphtheria pre-eminently toxic. The nexus between the morbific agent and the morbid process was in the one case dissemination, in the other diffusion. In both cases a fatal influence spread from a focus of infection, but in splenic fever the spread was by the multiplication and dispersion of myriads of bacilli, in the other by the slow contamination of the organism by a poison which it was convenient to call provisionally toxin, though perhaps a proteid, and certainly pre-eminently colloidal. We might, therefore, classify infective diseases in line, placing splenic fever at one end, tetanus at the opposite end, and the others in intermediate positions, according to the relative predominance of the toxic or biotic element in the action of the microphytic agent. We should bear in mind that every morbific microphyte acts primarily toxically, and that without toxical power no microphyte can live. Even in the case of splenic fever we had evidence that mitigated bacilli do not multiply, and are not disseminated in the bodies of susceptible animals, a fact which seemed plainly to indicate that the reason why virulent bacilli do multiply is that by their direct action on the tissues, and by thus surrounding themselves with an environment in which they can live, they acquire sufficient power to be aggressive.

Another point was that of the possible substitution of one species for another. Our studies led us to the conclusion that in certain instances the same kind of infective action may be exercised, and the same morbid process be initiated, by microphytes of different species—*i.e.*, that in these cases, although the intervention of some microphyte is essential in order to bring the morbific agent into existence, one may act as surrogate to another.

In concluding the course of four lectures, Dr. Burdon Sanderson said he had endeavored to show that although the first qualification of a disease-producing microphyte was the faculty of living and multiplying in the living tissue, the researches of recent years had taught us that its poisonousness was even more essential than its adaptedness to a living nutritive medium; so much so that the damage which it thereby inflicted on its living environment was a means by which it modified that environment for its own advantage. The contest in the organism between tissue elements and microphytes was not a hand-to-hand encounter, but rather one in which both acted at a certain distance, and one in which the weapons were poisons and counter-poisons—toxines and anti-toxines—words which merely implied that the physiological endowments of these bodies were antagonistic. The question of infection had become more and more chemical, but we guard against its being implied that any progress in the discovery of the chemical agencies by which diseases are produced and prevented can be made without the bacteriological method, or that it is in the least less necessary than before that all who intend to be pathologists shall perfect themselves in the technique which Koch created. If the questions which concerned us appeared to be chiefly chemical it meant only that we had got from the form to the substance, from the agent to the action. Pathologists were never phytologists, and did not pretend now to be chemists. We cared for microphytes not as botanical species, but as makers of toxines, and for toxines not as chemical compounds, but as producers of disease. As they were not organized we must call them chemical, but our chemical knowledge was so inconsiderable that the chemist would scarcely recognize their existence. They possessed certain nosogenic or alexiteric properties which appeared to attach themselves to proteids; but of their chemical nature the pathologist was able to say even less than the physiologists could of the so-called euzymes.

At the last meeting of the Medical and Chirurgical Society considerable interest was evoked by a paper from Mr. Lawson Tait entitled "Pleural Effusion in Association with Disease of the Abdomen." Mr. Tait said the object of his paper was to draw attention to the occurrence of pleural effusion as a condition occasionally associated with abdominal disease. The first case in which he saw the complication was one in which the disease proved to be a cancerous development in the ovary associated with secondary cancerous growth in the pleura, the result of which was that the pleural effusion had a sanguinolent character; a tentative operation to deal with the abdominal disease proved a failure, and the patient died. In other cases of abdominal disease in which there was pleural effusion of a bloody character, he had given a universally unfavorable prognosis and declined to operate on the ground that the complication was a certain indication of the presence of malignant disease. Mr. Tait related, however, a case in which there was double effusion into the pleural cavity of a markedly bloody character with ascitic effusion in the peritoneal cavity (also sanguinolent and associated with a tumor); the patient recovered from three tappings of the pleura, after which the pleural effusion did not recur. The ascitic effusion recurred after thirty tappings, and the patient's health improved so remarkedly that Mr. Tait determined to attempt to remove the tumor, which was the apparent cause; this proved to be a fibroid tumor of the ovary, which was removed quite successfully, and the patient's health remained perfect four months after oper-

ation. As no recurrence took place the author was inclined to regard the opportunity that he had in this instance of correcting an erroneous conclusion as a remarkable confirmation of the view he had often expressed, viz, that all cases of abdominal disease, however unfavorable, ought to have the opportunity of an exploratory or confirmatory incision.

An animated discussion followed the reading of Mr. Tait's paper. Dr. Hale White referred to a paper, by the late Dr. Hilton Fagge, in which the mysterious affinity between the various serous cavities was pointed out. Dr. Routh said the question raised was, "Was malignant disease of the abdomen present in every case of sanguinolent pleuritis?" The case quoted by Mr. Tait was one of benign tumor, and the pleuritis of children was often sanguinolent without abdominal disease being present. Dr. Griffiths said he had seen one case of pleural effusion associated with hydroperitoneum in which he had advised against operation; there was œdema of the lung and albuminuria. The operator, however, removed the growth and the patient got rapidly well. Dr. Frederick Taylor thought tubercle was the most frequent cause of effusion into both the pleura and peritoneum. The occurrence of blood in a serous effusion could not be regarded as a sign of malignant disease, for blood-vessels in a partly organized adhesion might give way. Mr. Barwell observed that malignant diseases of the pleura might exist without sanguinolent effusion. Mr. Tubby said experiments on animals went to show that the pleura, pericardium, and peritoneum were to be regarded as large lymphatic sacs communicating with each other. Dr. Herbert Spencer said pleural effusion was common in malignant disease of the abdomen and also in septic cases. Mr. Tait then replied and said his reason for producing the paper was that in conversations he had held with several physicians having much to do with diseases of the chest, he had uniformly been told that a serous pleural effusion containing blood in cases of chronic abdominal disease was of necessity an indication of malignant disease. He had believed that statement to be true until he met with his second case related, in which he had excluded all the ordinary causes of effusion, such as rheumatism or pyæmia.

HOW TO PRESERVE THE PERINEUM.

To the Editor of the Medical Record.

SIR: In the last issue of your valuable journal (December 5th) I was interested to see an article by Dr. N. W. Rand on "The Perineum: How to Preserve It." I agree with him that stretching of the vaginal orifice with the fingers is of value to prevent its laceration in primiparæ. This procedure has often been resorted to in this hospital, and always with good results.

But there is a statement in Dr. Rand's article which I cannot accept, and I think that the majority of obstetrical operators will also question its truth, viz., that "we almost invariably tear the perineums of primiparæ in instrumental deliveries." A friend of mine once told me that he had never seen a primipara delivered with forceps without laceration of the perineum; he had seen and had had in his own practice many cases. I have heard others make similar remarks, so Dr. Rand is not alone in thinking that the perineum must usually be sacrificed, if instruments are used upon a primipara.

The following statistics upon this point seem to me of interest. On looking through 600 cases occurring in the Sloane Maternity Hospital within a year past, I find that 46 primiparæ were delivered with instruments, viz., 4 craniotomies, 2 "high forceps," 10 "medium forceps," and 30 "low forceps." Twenty-eight of these 46 were not torn at all, 5 were so slightly torn at the posterior commissure that they need not be called "lacerations," while 13 (about twenty-eight per-cent.) were torn badly—varying from one centimetre in depth to a laceration as far back as the sphincter ani. Only two were torn to the sphincter—one was an ordinary "low forceps" with a very inelastic perineum, the other a case in which craniotomy was performed upon the after-coming head because of failure to deliver after podalic version, which was done on account of eclampsia and a deformed pelvis.

Such statistics form in my opinion a basis for believing that, if the perineum of a primipara is torn when instruments are employed to deliver, the operator is in the great majority of cases wholly to blame. Making the head advance slowly and observing the proper mechanism are the two main points ever to be kept in mind by the accoucheur, whether the delivery is instrumental or not.

Yours respectfully,
ERVIN A. TUCKER, M.D.,
Resident Physician.

Sloane Maternity Hospital, New York,
December 10, 1891.

To the Editor of the Medical Record.

SIR: In the article by Dr. N. W. Rand, on the above subject, in the Medical Record of December 5, 1891, I would like to add my testimony, as his method has been my routine practice in one hundred and sixty-three cases. That I was taught it in text-books or in college I cannnot remember, but the bedside has at least done so. I do not think it original, but believe it to be common practice. If there is a method above others by which the accoucheur can assist his patient this certainly takes the lead. It preserves the perineum, it strengthens pains, and shortens labor. It is not necessary in all cases that one attends. In multipara, when the perineum is soft, patulous, and easily dilatable, it will shorten and ease labor some, but it might be a meddlesomeness that might be called unnecessary. In primiparæ, the class in which there is always considerable danger of rupture, especially if compactly built and somewhat advanced in years, the method is of the greatest service, and, in my experience, will keep the perineum intact.

My method has been, too, invariably, after the second stage of labor has fully set in and the head begins to press upon the perineum, to press the perineal body with the index- and middle-fingers, between pains, firmly backward and downward. The pressure is or need not be painful, and the dilatation one makes in this way will always be plainly perceptible, the effect on the pains and mother always favorable, and the physician will not be in the state of terrible apprehension in which he is so often placed when he has his hand upon a thin, hard, and membranous dilatation, fearing that the pain will tear it in twain.

It does not only do all this, but even more in breech presentations. It often saves the life of the infant. In a breech presentation it is the best practice, as soon as you have made your diagnosis, to dilate with your hand the orifice of the vagina and the perineum, so that the head may be born as rapidly and safely as possible. It certainly seems to me that every accoucheur ought to have this fact suggested to him by the very conditions he so constantly finds at the bedside.

HERMAN GASSER, M.D.

Platteville, Wis., December 7, 1891.

Sauerkraut in Dyspepsia.—Dr. Heller, of Vienna, thinks he has found a remedy for dyspepsia in that well-known digestive tonic, sauerkraut. It is especially recommended to nervous invalids who suffer from eructations and flatulence after meals. Dr. Heller is not trying to be funny, but apparently means what he says. That may do for the German stomach, but, perhaps, the American dyspeptic would do as well to stick to mince-pie and hot soda biscuits, with an occasional Welsh-rarebit thrown in.

PNEUMONIA—ITS ABORTION.

To the Editor of the Medical Record.

Sir: In the Medical Record of May 2, 1891, appeared an article by Dr. Oliver J. Roskoten, giving his experience in aborting lobar pneumonia by the use of jaborandi. I desire to give some likewise apparently encouraging results in attempts at aborting the catarrhal as well as the lobar form of the disease. My main reliance is on ergot.

Not long since I met with three cases which at the time I considered catarrhal pneumonia in its congestive stage, but following the use of this drug the morbid process so speedily subsided that I thought that a mistake in diagnosis must have been made. I could not break away from the inbred idea that pneumonia must run its course to the end; but I resolved to observe closely in the future.

Within the past month it has been my fortune to meet with five additional cases, of various ages, which, in my opinion, were catarrhal pneumonia in its early stage, all aborted. In four the disease had only progressed to congestion, while exudation had occurred in one of the cases.

The treatment has been the same in these eight cases, except in the last five, in which, influenced by Dr. Roskoten's experience with jaborandi, I produced a more profuse and long-continued diaphoresis than formerly, using liquor ammoniæ acetatis, warm drinks, and applications instead of jaborandi when the age or physical condition of my patients contraindicated the use of that drug. While I consider sweating an important part of the treatment, yet inasmuch as on three occasions the disease was stayed when no marked diaphoresis was produced, I feel justified in considering the ergot the most effectual part of the medication.

The formula I use in pneumonias up to the time when the disease is thoroughly established is as follows:

℞. Ext. ergotæ fld..... ℥xx.
Tinc. aconite rad..... ℥i.–ij.
Liq. ammo. acet..... ʒ iiiss.
Syr. tolut..... .....q. s. ad ʒ ss.
M. Sig.: To be taken every two hours.

The dosage of the above is of course regulated to the age, but the same ingredients are used for all ages. This, together with mild counter-irritants to the chest, warm drinks and applications, the cotton vest, and such symptomatic treatment as each case required, has given me the results herewith presented.

Case I.—Georgie B——, aged three. Sickness began as a coryza on October 26th, followed by some coughing and a light fever on the 27th. He continued to grow worse, and I was called on the 28th.. At 10 P.M. I found pulse, 140; respirations, 44; temperature, 100.8° F. The alæ of the nose moved with the respirations; expiratory grunt. Percussion showed diminished resonance over the lower part of the left lung latero-anteriorly. Over this area auscultation revealed a roughened respiratory murmur and partially developed bronchial breathing. Other parts of chest gave evidence of bronchitis only. The next morning there was evident improvement in all symptoms, the temperature rising to 99.8° F. The day following this the temperature was normal. Percussion dulness had disappeared, the abnormal respiratory sounds receding more gradually. Convalescence was uninterrupted.

Case II.—Baby B——, aged two and one half months. Disease began as a bronchitis on November 1st, and so continued until the 10th, when it became much worse (when I was called), the infant just having had a convulsion. Breathing was rapid, cough painful, expiratory grunt after coughing, alæ of the nose moved slightly, temperature nearly 102° F. Impaired resonance on percussion over upper part of left lung anteriorly, with a localized roughened respiratory murmur and bronchial breathing; no râles other than those of bronchitis. The next morning there was less fever and evident improvement. Twenty-four hours later temperature was normal and respiration quiet, cough remaining, but less troublesome and frequent. Improvement steady, physical signs of disease entirely disappearing.

Case III.—Georgie B—— (same individual as Case I.). Taken sick as before with coryza November 9th, a light fever continuing until the 12th. I found the temperature, 100° F.; cough, respirations slightly accelerated, diminished resonance on percussion over lower part left lung (same area as was affected in the last sickness), localized rough respiratory murmur and bronchial breathing. In the afternoon the temperature reached 105° F.; pulse, 133; respirations, 44; and there was apparent dulness where the resonance had been only impaired slightly in the morning, marked bronchial breathing. The next morning the temperature was normal, but rose to 102.5° F. in the evening, with respirations reduced to 20 per minute. Dulness had disappeared, the localized roughened respiratory murmur only remaining. The temperature continued between 101.5° F. and 102.3° F. until the 15th, the distinctively pneumonic signs disappearing, dulness having entirely disappeared and the normal vesicular murmur taking the place of the rough and bronchial breathing. Large, moist râles over both lungs. On that date (15th) the temperature rose to 104° F., and respirations to 40. Physical examination showed that the area formerly affected remained normal, but above and anterior to it was a newly developed patch of dulness and roughened respiratory sounds. The ergot mixture, which had been discontinued on the 14th, was again prescribed, and in twenty four hours temperature and respirations were normal, and so remained. Recovery was steady and uneventful. physical signs of pneumonia disappearing, dulness first, then more slowly the abnormal sounds.

Case IV.—John N——, aged twenty; had had a cough for several days when I was called, November 13th, midnight. Temperature normal, respirations slow and labored, frothy yellowish expectoration, no dulness, whistling râles and large moist râles over both lungs. Evidently only asthma with bronchitis, and I prescribed for that condition.

November 14th, asthma improved, otherwise worse. Temperature, 101.7° F.; pulse, 120; respirations, 22. Profuse frothy expectoration, tinged with blood. Dulness over the middle portion of the left lung antero-laterally. Auscultation gives the same results as yesterday, except over the area of dulness there is bronchial breathing with fine, moist râles, also a localized increased vocal fremitus. In twenty-four hours the temperature was normal, and respirations 18; the expectoration had diminished in quantity and the color had changed back to yellowish-white. The chest was examined on the 16th; no subcrepitant râles or bronchial breathing or impaired resonance on percussion, only large, moist râles of bronchitis remaining. Convalescence was uninterrupted except by a trivial alimentary disturbance on the 16th.

Case V.—Mrs. R——, aged seventy seven, after symptoms of bronchitis for several days was taken, on November 14th with pain in the right side of the chest; cough, yellowish expectoration; temperature, 100.6° F.; respirations, 32; pulse, 98.

Percussion showed loss of normal resonance over the anterior surface of the upper part of the right side of the chest. Auscultation gave bronchial breathing restricted to the area of partial dulness. The characteristic râles of asthma were heard over both lungs. Increased vocal fremitus over the area of dulness. At my next visit, in eleven hours, the temperature was 97.6° F.; respirations, 22; pulse, 63. Dulness had vanished, but rough respiratory murmur was still present. This gradually gave way to the normal vesicular murmur. Recovery was uninterrupted, the temperature rising to normal and then remaining.

It is quite possible that Cases IV. and V. were of the lobar form of disease, although many facts, and especially the early history of the cases, militate against that theory. At times it is impossible to differentiate between the catarrhal and lobar forms.

In the above cases, in physical examination, careful comparison was made between the same areas on both sides of the chest. These cases are submitted without further comment, with the hope that the future will establish the promise that in ergot we possess an agent with which we may be materially assisted in successfully combating pulmonary inflammation in early stages.

Since the above was written I have been called again to Georgie B ——. He recovered from the last attack of pneumonia, only a slight cough remaining. He was taken sick for the third time this fall, November 28th. The next day, when I was called, the temperature was 102.9° F.; respirations, 34; pulse, 155; there was loss of resonance over the entire left lung anteriorly, and the lower part posteriorly; bronchial breathing over the entire lung; only large, moist râles discovered.

Under treatment in forty-eight hours there was marked improvement, the temperature being only one-half degree above normal, and respirations 25; there was a marked lessening in the degree of dulness, and a returning vesicular murmur over a large part of the affected area; bronchial breathing, although of less intensity, remaining at a few points.

The case here returned to the hands of the regular medical attendant of the family, who had been temporarily disabled.

R. T. STRATTON, M.D.

OAKLAND, CAL.

Therapeutic Hints.

How to Apply Trichloracetic Acid.—Dr. C. Wegele, writing in the *Allgemeine Medicinische Central-Zeitung*, recommends the following method for the application to a limited area of trichloracetic acid. He takes an ordinary tunnelled sound, nickel or silver plated, having a deep but narrow gutter, and engages one or more crystals in the anterior portion of the gutter by passing the sound into the bottle containing the acid and pressing it against the side. Then the sides of the sound are carefully wiped clean of any acid adhering to them, and it is ready for use. By this means it is possible to cauterize any limited portion of the nasal cavity, for example, without the danger of touching any other part with the acid.

Belladonna in Biliary Colic.—Dr. G. Sticker, of Cologne, finds belladonna a very useful remedy for the colic caused by the passage of a gall-stone. Its direct anodyne effect is much less than that of opium, but it seems to possess the power of rendering the subsequent attacks less frequent and less severe. The author explains its action by a paralyzing effect upon the circular muscular fibres of the ductus choledochus. The drug is especially indicated in those cases in which the stone has become arrested in the duct and the attacks of colic are frequent and moderately severe; but when the pain is excessive and symptoms of collapse are threatening, recourse must be had rather to opium. He gives a solution of the aqueous extract, gr. ij-iij. in one ounce of water, of which the dose is 20 drops every thirty to sixty minutes.—*Münchner Medicinische Wochenschrift*, No. 35, 1891.

Benzoate of Mercury for Buboes.—Dr. Nelander claims to have had excellent results in the treatment of buboes by the injection of benzoate of mercury (*Archiv für Dermatologie und Syphilis*, No. 3, 1891). In those cases which are not too far advanced he succeeds nearly always in preventing suppuration, and even when moderate fluctuation is present it is often possible to promote absorption by these injections, and thus do away with the necessity of an incision.

The Care of the Mouth.—In a recently published work Dr. Thomas, a German physician, calls attention to the great prophylactic value of buccal cleanliness. The best dentifrice, he says, is soap, which dissolves the mucus and removes it from between the teeth more thoroughly than any other substance. After a careful brushing with soap or with the tincture of soap-bark (quillaya saponaria), some antiseptic should be used. The most efficient antiseptics for this purpose, either of which is capable of destroying the micro-organism in one minute, are thymol, 1 to 25,000, and corrosive sublimate, 1 to 5,000. The following is recommended as a useful and pleasant buccal disinfectant:

℞. Thymol ..... gr. iij.
Benzoic acid ..... gr. xl.
Tincture of eucalyptus ..... ʒ iij.
Essence of peppermint ..... ♏ x.
Alcohol ..... ʒ iij.
M. Sig.: Pour enough in a glass of water to render it turbid and use as a mouth wash.

Hereditary Syphilis.—The following was used by Mr. Jonathan Hutchinson with good effect in the case of an infant, some two months of age, afflicted with hereditary syphilis (*Archives of Surgery*, vol. ii., November 8, 1891):

℞. Iodide of potassium ..... gr. ss.
Solution of bichloride of mercury ..... ♏ x.
Spirits of wine ..... ♏ iv.
Water ..... ʒ j.
M. Sig.: To be taken three times a day.

The liquor hydrargyri perchloridi of the B. P. has one grain each of corrosive sublimate and chloride of ammonium, in two ounces of distilled water.

Plaster-of-Paris Formulas.—1. *To Make Plaster Set Hard.*—Mix best plaster-of-Paris with about ten per cent. —more or less, according to effect ascertained by preliminary experiment—of very finely powdered marble (calcium carbonate). Or add to it about six per cent. of powdered alum, or about the same amount of ammonium chloride, before mixing it with water. 2. *To Make Plaster Set Slower.*—Mix it with two to four per cent. of powdered althæa root before adding the water. This not only retards the hardening of the plaster, but also enables it to be cut, filed, sawed, and turned. An addition of eight per cent. of althæa powder retards the complete setting of the plaster for about one hour, so that the mass can be used for any purpose where it is to remain plastic during at least a portion of that time.—*American Druggist.*

Old Tinctures.—Great care should be taken in administering remedies in the form of tinctures which have stood for a long time in small vials in the family medicine closet. When the bottles happen to be loosely corked the alcohol readily evaporates, leaving the drug in the form of a concentrated tincture, the pharmacopœial dose of which might produce very serious, if not fatal, results.

Œdema of the Glottis.—Pilocarpine has been used with good effect in œdema glottidis. The remedy is used hypodermically in doses of $\frac{1}{15}$ grain, at intervals of twenty minutes. Improvement is noted after the first injection, and usually not more than three doses are given before all dangerous symptoms have disappeared.

Irritability of the Bladder.—Powdered nutmeg has given good results in cases of irritability of the bladder from various causes. It is said that in South Germany, especially in Munich, this is a very popular remedy for dysuria, caused by the too free use of new beer. As much of the powder as can be taken on the tip of a knife-blade may be given several times a day.

Methylene Blue in Malaria.—Drs. Guttmann and Ehrlich publish in the *Berliner Klinische Wochenschrift*, No. 39, 1891, the results of some experiments made by them in the treatment of malarial fever by methylene blue. They used it in a few cases only, but found that it

exerted a most beneficial effect in cutting short the disease. The pyrexial attacks disappeared in the course of the first few days after the drug was exhibited, and within eight days at the longest the plasmodia were no longer to be found in the blood. The remedy was exhibited in gelatine capsules in doses of 1½ grain at intervals of from one to three hours until five had been taken.

Oil of Wintergreen in Gonorrhœa.—Dr. J. A. Wyeth has obtained good results in gonorrhœa by the administration of oil of wintergreen in doses of six drops three times a day.

Cyanide of Mercury in Diphtheria.—Dr. De Ruelle claims to have obtained good results in diphtheria by the internal use of cyanide of mercury, given according to the following formula :

℞. Cyanide of mercury..... gr. ss.
Alcohol (90 ..... ʒ jss.
Distilled water..... ʒ iv.
M. Sig. : A teaspoonful every hour.

Camphor in Influenza.—The following is said by Dr. Devereux (*British Medical Journal*) to have given more satisfactory results in the treatment of influenza than any of the more commonly employed remedies :

℞. Spirits of camphor,
Compound tincture of lavender.....ãã ʒ ij.
Spirits of chloroform..... ʒ j.
Mucilage of tragacanth..... ʒ j.
Distilled water ..... ʒ iij.
M. Sig. : Tablespoonful every four hours.

Uniting the Edges of Scalp Wounds Without Sutures.—Dr. Delassus says, in the *Journal des Sciences Médicales de Lille* for October 2, 1891, that he finds it of advantage to retain the edges of a scalp wound in apposition by means of the hair instead of sutures. When the hairs are long enough he ties together those on opposite sides of the wound ; when they are too short for this purpose, he has the edges of the wound held closely in apposition by an assistant, then places the hairs from the two sides in small twisted bundles, crosses them without attempting to tie them, and while they are held in this position tightly stretched, he passes a silk thread around them and ties it firmly. In this way the bundles from opposite sides of the wound are bound together, and thus obviate the necessity of an additional wounding of the scalp by the insertion of sutures.

Renal Colic.—The following has been recommended :

℞. Salicylate of sodium,
Bicarbonate of sodium.....ãã ʒ ij.
M. Divide into eight powders, one to be taken every hour.

Straw Ashes as a Material for Surgical Dressing.—Dr. T. Kikuchi, of the Japanese Army, writes in the *Sei-I-Kwai Medical Journal*, November 9, 1891, on the value of ashes obtained by burning rice straw as a material for surgical dressings. He finds that they possess the advantages of being rich in absorbent power, soft and elastic, cheap, aseptic, and easily obtainable. He reports several cases of injury in soldiers in which he used this dressing with good results. The ashes were enclosed in gauze bags of various sizes, and applied as desired.

Paraffin in Diphtheria.—Dr. Turner, of Gloucester, has obtained excellent results in the treatment of diphtheria from the local application of paraffin (*British Medical Journal*, September 19, 1891.) The applications are made every hour by means of a camel's-hair brush, and the ordinary oil used in lamps is employed.

There are One Hundred and Fifty-three Medical Journals in Paris, including eight pharmaceutical papers, and only one hundred and sixty-one papers of the lay press.

Aristol by insufflation is recommended by Dr. Fitzpatrick in the treatment of epistaxis.

New Instruments.

A SPLINT FOR FIXATION OF THE SHOULDER.

By RALPH CROSS HUSE, M.D.,
GEORGETOWN, MASS.

THE splint here shown was devised by me some ten years ago, for use in any case in which fixation of the shoulder is desired, as in fracture, or after excision of the head of the humerus. I send it to the MEDICAL RECORD, hoping it may be of benefit to other physicians ; any tin-worker can make it, at small expense. Its advantages are comfort to the patient, absolute rest to the parts, security of position, and simplicity in construction. It is strapped around the body by two pieces of webbing with buckles,

slung from the opposite shoulder, which gives it additional support, and allows the patient more freedom in getting about than anything I have ever met with. The results from its use are all that security, firmness, and comfort can contribute to bring about in the treatment of troubles to which this is directed.

The arm is strapped to the cylindrical part with the addition of any coaptation splint, and once the splint is in position the case goes on to recovery.

The splint should be right and left, or one for each side, well "rounded out" under the arm to fit the axilla, and the angle of the cylindrical, or arm part, may be fixed at the practitioner's fancy.

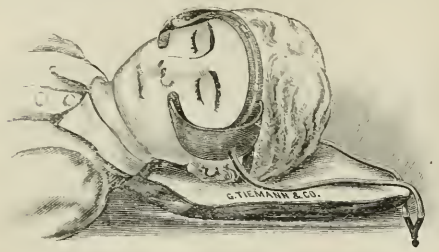
EYE-DRAIN AND IRRIGATOR FOR USE IN PURULENT CONJUNCTIVITIS.

By E. L. OATMAN, M.D.,
NYACK, N. Y.

THE greatest obstacle to the satisfactory treatment of acute destructive conjunctivitis, especially the severe purulent form, epidemics of which are frequently encountered in our overcrowded juvenile asylums, is the imperfect means and methods employed in cleansing the eyes.

That the eyes in such cases may be freely irrigated, without at the same time wetting the patients and bedding, I employ drains constructed as follows : The frame of flexible copper is covered with gutta percha, this passes across the forehead and encircles the eyes as far as the nose. To the sides are attached soft rubber cups which collect the waste fluid and discharge it through tubes into a basin on the floor. The flexible copper permits the apparatus to be accurately moulded to the form of the face, and its successful operation will depend on the care with which this is done. An adjustable steel spring fitting over the frame presses it firmly against the cheeks. The spring is made separately and only applied during the cleansing process, as its long-continued press-

ure might prove painful; although if intelligently adjusted, with only sufficient force to prevent leakage, it may be worn continuously for hours or days.



When it is desirable to keep a gentle stream of water, hot or cold, flowing constantly over the lids, and the patient cannot command the undivided attention of a nurse, I use an irrigator in which the fluid is delivered through a rubber tube wound outside with stout soft copper wire. Such a tube when bent will retain its position, and we are thus enabled to discharge the stream in any direction, or at any angle. An iron frame attached to the head of the bed supports the tube and a reservoir.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 6, 1891, to December 12, 1891.

FISHER, WALTER W. R., Captain and Assistant Surgeon. Relieved from duty at Fort Assiniboine, Mont., and ordered to Fort Columbus, New York Harbor, for duty at that station.

WOODRUFF, CHARLES E., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Missoula, Mont., and ordered to Fort Assiniboine, Mont., for duty at that station.

PATZKI, JULIUS H., Major and Surgeon. By direction of the President, will report in person to the President of the Army Retiring Board, at Fort Leavenworth, Kan., for examination by the board.

TAYLOR, ARTHUR W., Captain and Assistant Surgeon. Having been found incapacitated for active service, is granted leave of absence until further orders, on account of disability.

SHILLOCK, PAUL, First Lieutenant and Assistant Surgeon. Granted leave of absence for fifteen days.

HOPKINS, WILLIAM E., Captain and Assistant Surgeon. Resignation accepted by the President, to take effect April 5, 1892, and granted leave of absence to include that date.

MIDDLETON, PASSMORE, Major and Surgeon. Having been found incapacitated for active service by reason of disability incident to the service, is, by direction of the President, retired from active service.

Official List of Changes in the Medical Corps of the United States Navy for the week ending December 12, 1891.

MORRIS, LEWIS, Assistant Surgeon. Detached from the Navy Yard, League Island, Pa., and ordered to the Receiving Ship St. Louis, at that yard.

HARRIS, H. N. T., Assistant Surgeon. Detached from the Receiving Ship St. Louis, and ordered to the Navy Yard, League Island, Pa.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 12, 1891.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	28	5
Scarlet fever	157	22
Cerebro-spinal meningitis	1	2
Measles	70	8
Diphtheria	120	31
Small-pox	0	0
Varicella	12	0
Pertussis	0	4
Erysipelas	1	0
Mumps	1	0
Rötheln	0	0

Benzoate of Naphthol β, a New Intestinal Antiseptic.—The insolubility of the higher aromatic compounds has till recently been a great obstacle to their study as antiseptics. The naphthols, especially naphthol β, have been for some time administered as intestinal antiseptics, but it was soon found that a compound of naphthol β with salicylic acid, introduced under the name of betol, was more efficient. This substance varied considerably in composition, and was also inadmissible when on account of renal disease salicylic acid was contraindicated. Other organic acids will, however, form similar compounds with naphthol β, and Yvon and Berlioz (*Sem. Méd.*, October 28, 1891) have fixed upon benzoic acid as likely to form a useful combination, for it is less toxic and a more powerful antiseptic than salicylic acid. By treating naphthol β with benzoyl chloride under certain conditions and purifying by crystallization, from alcohol they obtain a compound which is a benzoate of naphthol β, or "benzonaphthol," soluble in alcohol or chloroform, but very feebly soluble in water or ether. This compound when introduced into the intestine breaks up into naphthol β (which remains in the intestine) and benzoic acid, which is eliminated by the kidneys in the form of alkaline salts and alkaline hippurates. Although at present experience with the new drug is somewhat small, the following conclusions may be stated as to its action: 1, It is very slightly poisonous; 2, it is an antiseptic as powerful as its congeners; 3, it encourages diuresis, the absorbed portion being rapidly eliminated by the urine; and 4, it can be given in large doses, but it is advised to give small and frequently repeated doses rather than single large quantities. More than a drachm daily has been administered to an adult.

A Medical Centenarian.—The death is reported at Bordeaux of Dr. Stanislas Zalewski, a Polish refugee. Born in 1780, on Christmas Day, he had consequently at his death almost reached his 111th year. This veteran was a scion of the once powerful house of Zalewski, whose estates were confiscated by the Russian Government. Banished from his native land, Dr. Zalewski practised medicine for a long series of years at Bordeaux; thirty years ago, however, the encroachments of old age compelled him to resign practice. Since his retirement he had subsisted on a very modest pension allowed him by the government of his adopted country. His historical *souvenirs* were, as might be expected, most interesting, reaching back to the tragic events that marked the close of the last and the early part of the present century. Thus, he saw Napoleon the First reviewing his army at Moscow; and, peering timidly through a window and nestling against his weeping mother, he was a witness of the execution of Louis XVI. Until quite recently this relic of a past age enjoyed good health, and his faculties are said to have remained unimpaired to the last.—*The Lancet.*

DIET AND EXERCISE IN THE TREATMENT OF SIMPLE CHRONIC INFLAMMATION.[1]

By J. C. MULHALL, M.D.,

ST. LOUIS, MO.,

PROFESSOR OF DISEASES OF CHEST AND THROAT, BEAUMONT HOSPITAL MEDICAL COLLEGE; CONSULTANT IN CHEST AND THROAT DISEASES TO ALEXIAN BROTHERS' HOSPITAL, ST. MARY'S INFIRMARY, SOUTH SIDE DISPENSARY; MEMBER OF THE LARYNGOLOGICAL AND CLIMATOLOGICAL ASSOCIATIONS.

THE subject of my remarks is apparently commonplace, yet many experiences with patients force me to conclude that the dietetic and general hygienic management of individuals with chronic inflammatory disorders is either totally neglected, parenthetically mentioned, insufficiently explained, or made of secondary importance to treatment by drugs by a large number of physicians.

Yet I venture to lay before you the proposition that for the cure—real, not transitory—of a chronic inflammation, surgical treatment excluded, nine-tenths of the success will be due to skilful dietetic and hygienic management, and one-tenth to drugs, locally or systemically applied.

To select a common example, chronic nasal catarrh. I beg to declare that, atrophy, deformity, or permanent obstruction being absent, the above proposition is strictly correct; that the correct management of clothing, food, exercise, atmosphere, skilfully applied according to individual cases, will do nine-tenths, and medication, local and systemic, one-tenth, of whatever good may be accomplished.

The testimony of many patients, that the selection and preparation of their food, the manner and amount of physical exercise had not been insisted on by former medical advisers form the ground for my assertion.

If, then, my proposition and assertion be true, no further apology is necessary for the triteness of my subject.

It may be stated, broadly, that the vast majority of simple, non-specific chronic inflammations in the human body are caused by the faulty habits of the individual. There are exceptions. For example: where the intensity of an acute process has produced such anatomical death that regeneration of tissue is impossible; to illustrate my meaning, that incurable disease, atrophic rhinitis, rapidly following diphtheritic or scarlatinal rhinitis. Trace the life of an individual, from a hygienic standpoint, with constipation, hæmorrhoids, leucorrhœa, endometritis, intestinal or stomachic indigestion, hepatitis, myocarditis, bronchitis, laryngitis, pharyngitis, rhinitis, eczema, neurasthenia, and a host of other disorders, and you will find in one or many ways that the laws of health have been long and grievously transgressed. The one has been overfed, underfed, or badly fed, the other has neglected physical exercise. All other causes combined, including alcoholic excesses, are as nothing when compared with errors in diet and exercise in producing simple chronic inflammation.

It is to these two causes, dyspepsia and perverted nutrition, physical inactivity, and toneless muscles, nerves, and glands, that I attribute the extraordinary prevalence of chronic nasal catarrh in the United States. Our climate, our macadam streets, our furnace-heated houses, are but subsidiary to these two great primal causes. I have lived in many countries, and nowhere are candy, pastry, ice-water, and hot bread consumed as by my countrymen, the Americans. In no country is food bolted so hastily; and, to heap error on error, nowhere is less attention given to physical exercise. Let me give an illustration that may also serve to dissipate reproach to our St. Louis climate. Eighteen months ago, a young gentleman of this city, Mr. Clark T——, came to me with the following history: From the age of twelve to twenty he had been a sufferer from more or less distressing chronic nasal catarrh. He had been subjected to much local treatment with but temporary relief. At the age of twenty he accepted a position in a small town in the State of Kansas. In the course of a year, without treatment, his nasal symptoms disappeared, and he remained well until, at the age of twenty-four, he returned to St. Louis. In the course of six months his old symptoms reappeared. He consulted the same specialist, but without relief. He naturally concluded that the St. Louis climate did not agree with him and had concluded to return to Kansas. I found him a plethoric, robust man, suffering the usual train of symptoms of chronic hypertrophic nasal catarrh, including violent and frequent headache. Direct questioning elicited the following: In Kansas he earned fifty dollars per month, out of which he clothed and boarded himself, was occupied in a bank from nine until three, and spent a part of nearly every day fishing or shooting.

In St. Louis he earned double the salary, out of which he did not pay for board and lodging, since he lived at his father's house, a wealthy man, fond of supplying his table with every luxury. The son was occupied from eight till six, and he never walked to or from business, in fact, took no physical exercise.

There was therefore, on the one hand, in Kansas frugal diet, short business hours, much exhilarating exercise in the open air, and no temptation to dissipate; and on the other, a rich and generous diet, no physical exercise, and more money to gratify the desires which the late hours of a large city spread before one. When I presented the two pictures to him he agreed that there might be other factors besides the relative atmosphere of the small Kansas town and St. Louis.

His face suffused easily on exertion, his bowels were inactive, his urine turbid—in a word, here was an individual in a high state of hypernutrition with defective elimination. Tonsils, pharynx, and nasal erectile tissue were in a state of vascular engorgement. How absurd to think of curing such an individual with local treatment! I was reminded of the advice of the great Abernethy to the rich and corpulent dyspeptic, "Earn a shilling a day and live off it."

He was ordered to live as he did in Kansas, all the luxuries of the table were denied him. He was ordered to walk rapidly two miles in the morning, and the like distance in the evening. From twelve to one, his lunch hour, he joined in the calisthenic exercises pursued at the Missouri Gymnasium, and partook of a very light lunch.

The hypertrophied areas in nose and throat were destroyed with the galvano caustic, beyond which no local treatment was adopted. His diet and exercise were carefully regulated from time to time as I judged best.

This training process lasted six months, and ended in complete recovery. For the past year his weight and

[1] Read before the St. Louis Medico-Chirurgical Society, St. Louis Medical Society, and Missouri State Medical Association.

height correspond, he is stronger, though he weighs twenty pounds less, his bowels are regular, the urine clear, his nostrils unobstructed, he has not had a single headache, and in his case the question so often asked, "Is catarrh curable?" has been answered.

Here I may mention another case of nasal trouble, where the blunder of pursuing local treatment, to the exclusion of hygienic measures, merely increased the distress of the sufferer. Two years ago a policeman, aged fifty, consulted me, complaining that for several months he had suffered from "catarrh," as so called by two rhinologists who had assiduously sprayed his nose, to his increasing discomfort. The nasal discharge was profuse, like distilled water, occasionally mucoid in character, saturating from three to ten handkerchiefs daily. The nasal mucous membrane was found to be pallid and very irritable, the picture not of an inflammatory trouble, but of a vaso-motor paresis; other symptoms pointed to the disorder as a neurosis. His head and neck sweat easily, his face paled and flushed without apparent cause, the pupils were sluggish, he was nervous, he did not sleep well, and had grown quite irritable. In my endeavor to discover why a man, who all his life had enjoyed good health, had for several months past presented this array of symptoms, I found that for fifteen years he had been a mounted policeman, but that for the past eight months he had been relegated to a stuffy little office to do clerical labor. What a tremendous change in the life of an individual! His nose was not touched, no drug was administered. An explanation to the proper authorities secured for him a return to his horseback life, and within a month every morbid symptom had disappeared. I have seen him within a month and the cure remains perfect.

The good influence of diet and exercise has been remarkably exemplified to me in the persons of two prize-fighters, who applied to me for the treatment of chronic nasal inflammation. Nearly all of these men, in the intervals between their prize ring encounters, are in a state of atonic hypernutrition from excessive eating and spirit drinking, combined with physical inactivity; their bodies are filled with effete material. These men had tried many kinds of local medications, regular and irregular, with little or no relief, but both admitted, on direct questioning, that they had experienced absolute relief after they had undergone a system of training preparatory to entering the prize-ring for an encounter. Both again admitted that, after several weeks' return to their former bar-room lives, all their nasal symptoms reappeared.

Mr. B——, aged thirty-six, senior member of a well-known firm of wire-rope makers in this city, will tell anyone who asks him the following: He had for several years suffered from obstructive nasal catarrh, with viscid mucus and aching brows. He received local treatment at the hands of two specialists without relief. He began playing hand-ball three times weekly, finishing after each occasion with a shower-bath and vigorous rubbing. I shall not delay to explain why hand-ball is one of the finest of physical exercises. It completely cured him in three months of his nasal troubles.

Lest some critic, idiotically carping, should suggest that all cannot become prize-fighters or hand-ball players, I here say that I adduce these as illustrations of the soundness of my argument, as to the value of exercise in the cure of chronic inflammation. Let any of my hearers who, while he has not an acute coryza, has a feeling of dryness and stuffiness in the nostrils, take a rapid walk of two miles, and he will find that his nostrils have become freer, their mucous membrane moist, and there will be impressed on him the idea that chronic exercise may cure chronically stuffed noses.

I incidentally mentioned simple chronic endometritis. A lady friend and patient lately informed me that one of our best known gynecologists had packed the vagina with variously medicated cotton tampons and painted the wound weekly for fifteen months, with absolutely no success. What a loss of time and money and respect for the medical profession! She placed herself in the hands of two women doctors, who, practising hygiene of the body alone, without touching womb or vagina, cured her. What a comment on the absurdity of drugs as compared with an enforcement of those laws of nature which control elimination and assimilation, and equalize vascularity in the organs! The American woman with her crooked womb cannot exercise, because it produces dragging pains in her back, and there is nothing left for her but a pessary and a drug.

The most magnificent tonic for the sluggish pelvic organs is the Swedish movement-cure, a series of movements designed for the cure of chronic constipation, a condition very common in our American women, and one which all the drugs on earth will not cure. When, incidental to chronic affections of heart, lungs, or throat, I have encountered chronic constipation, I have made it a rule to first cure, if possible, this latter condition, and I cannot praise too highly the Swedish movement-cure. After two or three weeks, a daily evacuation is secured, when two or three of the movements, with dieting, will secure daily evacuation. I do not mean to imply that the science of gynecology can be reduced to a hop, skip, and a jump; I but wish to say that in simple chronic womb inflammations, as elsewhere in the body, diet and exercise are by all odds the most important of curative measures. The Swedish cure is a proof that there is a scientific method of prescribing exercise.

Disorders of digestion frequently exhibit pathological reflexes on the respiratory track. The dyspeptic throat is fairly well known, but I have yet to read of the dyspeptic nose. If disorders in diet and exercise will produce piles in some individuals, why will not like errors, in other individuals, produce vascular changes in the nasal erectile tissue, where the cavernous sinuses have even less support than in the rectum? Over and over again have patients with nasal catarrh admitted to me that faulty digestion aggravated the nasal symptoms. Several have given me the curious information that the nasal discharge, always odorless, became fetid when suffering from bilious attacks.

All the great operatic singers are aware of two facts: one, that they cannot sing with precision after a full meal, the other that a bilious attack may entirely deprive them of the power of singing their scores. The soft parts in the larynx seem puffy, the cords are congested, the laryngeal movements lack snap and vigor. Local treatment merely aggravates such a condition.

Starvation diet, vigorous exercise, a blue pill followed by a saline, and the vocal disabilities disappear. How easy to understand that the cure of chronic stomach or intestinal catarrh may be of every importance in the treatment of chronic laryngitis or pharyngitis! The latter is very seldom a primary disorder; a mucous membrane so constructed as to admit of the tri-daily friction of food does not readily yield its health. Chronic pharyngitis is often but the expression of a disordered alimentary canal. I have known it to disappear after the cure of chronic constipation. Local treatment usually aggravates, never cures, the dyspeptic throat. Let me here cite an instructive case, as it not only exhibits the cure of such a throat, but the cure of several co-incident ailments.

Mr. P——, of Hannibal, Mo., consulted me last year concerning his throat, about which he had become disheartened, since he had submitted to tri-weekly local applications, extending over a period of three months, without relief. He also had insomnia, loss of memory, piles, constipation, flatulence, with occasional wandering pains. He was six feet high and weighed two hundred and fifty pounds. These symptoms and increase of weight were co-incident, and had accumulated within five years. Previous to this he had been a carpenter, undergoing physical labor every day, and subsisting with his family by the sweat of his brow. At that time he had

suddenly grown comparatively wealthy, abandoned all physical labor, and had since lived on the fat of the land. With his wealth and luxurious habits began his ill health. He was placed on a frugal diet, given daily severe exercise, lost forty pounds in three months, when every morbid symptom disappeared. No kind of medicinal treatment was pursued.

When such reflex hyperæmias have existed sufficiently long, solid hyperplasias often result, and these can be seldom removed by any system of hygiene, and must be attacked surgically. In nose, pharynx, and larynx such thickenings can easily be removed, but the bronchial tubes are inaccessible, and the hypertrophied mucous membrane often remains in spite of the utmost precision in the hygienic life of the individual, including appropriate climatic aid. Drainage is not here so perfect as in the upper air-passages, and again, chronic bronchial catarrh is very frequently the sequel of an acute attack in childhood which has produced irrecoverable anatomical change; still, the results obtained by perfect hygiene are far more brilliant than those resulting from medication. As an example of dyspeptic bronchial tube, I have often seen the following clinical picture: A patient complains of having "caught cold" in his chest. He has had a subacute bronchial catarrh. It has persisted several weeks and its obstinacy alarms him, the more so that other such attacks have persisted but a week or two. He has taken the usual expectorants, used counter-irritation, but the cough persists; he finds his tongue flabby and coated, food is repugnant to him, his bowels are sluggish, his digestion is bad—in a word, he is "bilious." The correction of this evil is at once followed by a disappearance of the cough. Expectorants can but aggravate the digestive disorder, unless they perchance produce vomiting and complete loss of appetite.

I have in my own person a mild type of chronic bronchial catarrh, caused, I think, by the inhalation of tobacco smoke, pursued now for twenty years. My expectoration is mucoid, and so easily expelled that I am hardly conscious that I cough. I have had occasional bilious attacks, and invariably on these occasions my cough tightens, the mucus becomes viscid, acquires a musty taste, and is difficult of expulsion. I have, by patient inquiry, elicited the same facts from a large number of sufferers with chronic bronchitis. Such clinical facts clearly indicate the influence of digestive disorders upon those within the chest, and should make us pause before rushing to the prescription blank. When all the excretory functions of the bronchitic are physiologically active, when his constipation has been cured, when his skin is made insensitive to temperature changes, when his food and exercise have been regulated to a nicety, these are the true expectorants and tonics.

If we consider the functional and organic diseases of the heart, my experience is that it is very seldom that a former medical adviser has not been careful to inquire into the condition of stomach and bowel in the functional cases, but that very frequently in the organic cases the health of the alimentary canal has not been supervised, nor has exercise been scientifically dictated.

The long, sighing inspiration, the flatulent sigh, the sense of oppression in chest or throat, the dyspnœa caused by the stomach distended with gas, is explained, I think, as follows: The inflation of the stomach with gas causes it to press against the bases of the lungs, thus mechanically interfering with the oxygenation of the basal air-vesicles during quick respiration. The patient then feels a sense of air-hunger, and a long forcible inspiration follows, which for a time sufficiently aerates the oxygen-hungry vesicles at the pulmonic bases. This balloon-stomach also mechanically interferes with the movements of the heart, and its irregular action often ensues. The fluttering heart, the chest oppression thus produced, cause the patient to suspect heart disease. I have twice been called to see rheumatic subjects, in consultation, where such a condition had suggested beginning cardiac rheumatism. In one the tympanitic note was elicited even in the left axilla, and at mid-sternum. A stomach-tube quickly restored peace. I have known this balloon-stomach to produce convulsions and unconsciousness. I can only explain the fact that the gas does not escape by assuming that the distention must produce at the pyloric or cardiac orifice, as frequently at the entrance to the œsophagus, spasmodic stricture.

Oertel was the first, I believe, to dispel the old illusion that patients with certain organic affections of the heart should beware of active physical exercise, and his hill-climbing and dietetic treatment in such cases has obtained world-wide recognition and endorsement. Many such patients are condemned to a life of physical inaction by their physicians. The consequence often is that they increase in weight, their muscles become flabby, their systems full of effete material, their capillaries become turgid, their ventricles more and more engorged during diastole, necessitating increased activity during systole, with final lack of compensation. Such a condition often explains why one patient with a certain valvular lesion soon becomes dropsical, while another with the same lesion, but whose diet and physical exercise have been nicely adjusted, goes on for years and years attending to the ordinary duties of life, experiencing little or no evil results from his leaking heart. In no other class of patients is it more important that the weight of the individual should conform to his stature. Every pound of physiological over-weight imposes just so much more labor on the heart. Such an organ, that must supply thirty pounds of useless over-weight, has imposed on it night and day a useless, wearisome labor that finally tells on its muscular fibre.

It is the physical training of the pugilist which enables his heart to withstand the mighty strain that a prolonged encounter puts upon it, and many a fight has been lost by a pugilist for lack of skill in his trainer in preparing his pupil's heart. Once more let me add that I am not endorsing a system of physical training such as pugilists, oarsmen, and athletes generally, undergo in preparing for their events. On the contrary, I am quite sure of the evil effects of such a course. The youth who adds three inches to his biceps with six months of exercise has a badly developed biceps. The flat chested individual who, as a prophylactic measure to phthisis, develops the girth of his chest three inches within six months, will have an improperly developed chest. Nature resents such sudden attempts at development. While enthusiastic in the knowledge of what physical exercise may do for health, no one is more cautious than I in the way in which it should be done, in each individual; for no laws that govern all cases can be given.

Why are so many physicians neglectful in the matter of prescribing physical exercise? One reason is, I think, in their manner of recommending it. The usual advice is, "you must take more exercise." This usually enters one ear, makes a faint impression on the cerebrum, and departs from the other. Exercise should be prescribed accurately, just as accurately as a drug. If the patient be told that he must walk forty blocks per day, at a certain rate of speed, this is definite advice; and so with whatever exercise is enjoined, its art, manner, duration, degree, and persistence must be explained and insisted on. I tell my patients that unless they do exactly as I dictate, they must in no sense hold me responsible for failure to cure. It is not the fault of our science if the business man or housewife declares he has no time to exercise. It is much easier to take pills, but they will not cure simple chronic inflammation. A dozen houses in our country find it profitable to manufacture pepsine, a drug that merely plays with the physiology of the stomach, a drug that nearly always is prescribed in the imbecile effort to replace diet and exercise. Three quack medicines flourish in the United States where one does in any other civilized country; ours is the country of dyspepsia and catarrh. The American believes in drugs, and that

charlatans discover combinations which the scientific physician cannot. He believes that for every physical evil there exists an antagonizing pill.

Another reason why medical men are careless in advising physical exercise is, that many of them have never experienced in their own persons any kind of physical training. I do not wish to say that a doctor must be a gymnast in order to understand the wonders of physical exercise, but I will be understood when I say that, what one has experienced in his own person is so impressed on him that he in turn is far more apt to impress the like on his patients. Moreover, a personal experience in all methods of physical training naturally gives one a better knowledge as to the method and amount of exercise which should be prescribed to meet a given indication.

To intelligently prescribe exercise presupposes on the part of the physician an excellent knowledge of physical diagnosis. He will commit many a mistake who is not expert in determining the condition of heart and lung. Oertel has reported some brilliant successes in his hill-climbing and dietetic treatment of certain organic heart diseases. How could he select fit cases and determine their progress were he not a master of physical diagnosis? As I have before said, physical exercise is potent for evil as well as good, and no one but a physician, in all that this word means, is the ideal trainer of the bodies of men. I do not pretend in this paper to go into the details of prescribing exercise, but I cannot refrain from mentioning two points. One is, that the exercise should not be selected which is sure to be abandoned after a while, and the other, that the exercise should if possible divert the patient's mind from the fact that it is exercise. The game of hand-ball is one of skill and pleasure, and hence is robbed of the incubus which men often feel when they are conscious at the time that they are exercising for the sake of health.

Just as with exercise, so with diet. Many physicians are not painstaking and exact in their advice. A case will illustrate. I lately congratulated a lady friend, who had always been a sufferer from some ailment, on her appearance of health. She assured me of her perfect health, and declared her gratitude to Dr. Hardaway, whom she had consulted for some disease of the skin, and who found it necessary to cure her dyspepsia, to which she had been a martyr for years. He succeeded in this where others had failed, and her explanation was as follows: "The other physicians all told me I must diet, but Dr. Hardaway was the only one to write down what I could eat, when I could eat, and how it should be cooked."

To simply tell a patient to diet himself is usually utterly meaningless to him. He must be informed about every article of diet, and frequently how it should be prepared. This presupposes on the part of the physician knowledge, not only of the nutritive value and digestibility of the various foods, but also a certain knowledge of the art of cooking; for the method of preparing food creates dyspepsia as well as the nature of food. Many physicians have no time to go into such detail. I may inform them that the great London physician, Sir Andrew Clark, takes the trouble to write out these things for his patients. He has no printed dietary. Every patient has peculiarities that modify prescriptions of diet and exercise.

If the patient be an invalid totally incapable of exercise, how important it becomes to enter into every detail of diet!

It matters little to the hod-carrier whether his food be indigestible or badly cooked. He is ignorant of the existence of a stomach, earns his bread by the sweat of his brow, and digests pork and cabbage or raw oysters equally well. When physical exercise is indulged in freely the matter of diet is not of much importance. The dyspeptic business man who goes on a shooting trip shortly finds that he may eat what he pleases.

Let me here enter a protest against the mid-day dinner of the American business man. He selects, if it be a good one, the restaurant closest to his place of business, as this saves time and walking. He eats a solid dinner, always hurriedly, for he is in the midst of his business day; he rushes back to his office, crushing the natural inertia following a full meal, and before digestion is fairly commenced his brain is whirling in the excitement of making the almighty dollar. I believe that this custom alone causes an enormous amount of disease. Is it not reasonable to assume that the heavy meal of the day is better eaten when the day's work is done, when one can take time to eat, surrounded, perhaps, by the cheerful influence of wife and children, and afterward quietly sit and give digestion a chance. Every animal, including man, is disposed to mental and physical quietude after a full meal. Mothers often protest against the late dinner for their children, on the plea that they would not sleep or digest well. I have nearly always found this observation based upon imperfect reasoning. Such children do not sleep well after a hearty meal because of enfeebled stomachs, produced by long-continued improper diet. The child which has been reared with strict regard to proper diet sleeps peacefully, even directly after a hearty meal. The English child gets stale bread, the American child is allowed hot bread, to give a single illustration of the different plans pursued.

When we analyze the conditions of longevity from practical experience, we always find two factors, temperance in food, and habitual out-door exercise. The lives of Gladstone, Bismarck, Von Moltke, De Lesseps teach us that work does not kill. But, as each relates, each found time for daily physical exercise. Bismarck, alone, somewhat intemperate at table, was restored to health by a strict dietary.

In saying what I have about the influence of exercise and diet, and other hygienic measures, in curing simple chronic inflammation, and the slight value of drugs, I am not reciting theoretical convictions, but telling actual living experiences, based on observations continued for many years.

SOME POINTS IN THE ANATOMY AND PHYSIOLOGY OF THE UTERUS, WITH SPECIAL REFERENCE TO THE ADENOID CHARACTER OF THE ENDOMETRIUM.

By STEWART PATON, M.D.,

NEW YORK.

Comparative anatomy and physiology are of little aid in the endeavor to define and limit the functions of the human uterus. The lessons they teach are merely suggestive, while they only emphasize one fact, viz., the dissimilarity between the menstruation and the œstrum or rut.

In spite of Dr. John Brown's lament, that man's superiority over the lower animals has been called into question by Sir William Turner's discovery of the hippocampus minor in the higer apes, women should experience far less humiliation. Anatomy has drawn sharp lines of demarcation between the human uterus and that of the lower animals, and the complex phenomena of menstruation in women certainly makes her "one farther remove from her anthropomorphic cousin."

There is a singular break in the structural evolution of the human female sexual organs as we trace their transitions, beginning with that large class of fish in which the ovaries are simply nothing more than tubular glands with attendant ducts. Rising in the scale we find the ovaries no longer supplied with continuous ducts, but the Mullerian ducts are subjected to such modifications that an oviduct is supplied for the passage of the ripe ova. Then there is a stationary stage, for it is not until the samopsida are reached that, in the modified Mullerian ducts or oviducts can be seen in the dilatation of the lower part of the tube a suggestion of the mammalian

uterus, which only exhibits important morphological changes in the didelphia and monodelphia.

In the primates the uterus, and more particularly the endometrium, attains a degree of development, which in morphological characteristics as well as in physiological function are distinctive of the higher form of mammalian development. In the structure of the human endometrium can plainly be seen some of the causes of the phenomena which are characteristic of menstruation.

In its life-history during the three periods of development, of activity, and of decline, no organ in the human subject has attracted more interest from the anatomist,

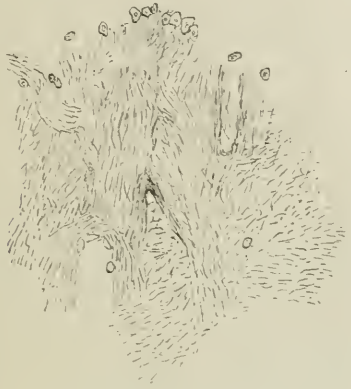

Fig. 1.—Endometrium of Infant, Aged Two.

the physiologist, and the physician than the uterus and its appendages. The early suggestions of Hank and Spiegelberg, and later the confirmatory and original work of Johnstone, Sutton, and Tait, have awakened new interest and not a little surprise in classifying the uterus with the cystogenic or glandular organs, and of depriving the endometrium of its claims as a mucous membrane. Upon the work of Johnstone and Sutton further study of the endometrium must be based.

It is very difficult to obtain a satisfactory section of the human endometrium. We found the most satisfactory sections were those obtained by using a freezing microtome, and the fresh sections were examined unstained. The accompanying sketch (Fig. 1) was taken from the section of an endometrium of a child, aged two. It is an additional demonstration of what Johnstone has already proved, the fibrillar character of the structure and the almost complete absence of cellular development. Contrast with this section one cut from a mucous membrane in any part of the body, and how great the actual histological differences as well as developmental history! As Johnstone has said, the various changes through which the endometrium passes certainly suggest that cell division is not the sole process responsible for the development of normal adult tissue. In the absence of positive proof that the cellular elements of the blood are actively concerned in the restoration of tissue we are forced to accept one of two conclusions, either that the restorative process is inexplicable, or that in the silent growth of the granule to the fully developed cell we have adequate interpretation of a seemingly complex process. If we do not accept this interpretation, how can we explain the replacement of the fibrous lining of the infantile uterus by what we may call the corpuscular endometrium of the adult organ. If we examine under the microscope sections of the endometria of women who have died during the period of menstrual activity or during pregnancy we find nothing to warrant us in classifying the endometrium with membranes of the mucous type. Curiously enough, it was once supposed that the ovaries were simply tubular glands, and while that has been disproved we might with far more propriety than was justified in the classification of the ovaries transfer the description to the uterus.

It is interesting to compare the normal adult endometrium with the endometric development of pregnancy. The normal endometric changes during menstruation consist in a casting off and subsequent renewal of the corporeal columnar epithelium without any true solution of continuity. It will be remembered that the process is confined to only a portion of the epithelium lining the utricular follicles, and the cervical cells are left intact, as well as the epithelium of the tubes. In the formation of the decidua of pregnancy similar changes occur, differing only in degree, the decidua vera and reflexa remaining perfectly distinct at the cervix. The analogy does not cease here, for it is now known that the changes of the glandular epithelium during pregnancy are largely limited to the cells nearest the mouths of the glands and in the intra-glandular tissue which is filled with the large decidual cells of Friedlander. The cervix is supplied by the spinal nerves, while the body is under the control of the sympathetic, and probably, as we shall see later, of contained automatic ganglia. With these facts in mind we are warranted in regarding the renewal of the endometrium as a physiological and not as a pathological process. To attribute to a mucous membrane the power of self-denudation and self-renewal has no analogy in any part of the body. The appearance of the endometrium during the intra menstrual epoch is most indicative of its adenoid character, for there is such a disappearance of the cellular elements that it strongly suggests the infantile fibrillar endometrium observable before menstruation begins. Even in the carnivora and herbivora, toward the end of the rut, as Johnstone first pointed out, and as we have ourselves observed, similar changes occur; an increase of the fibrillar and a decrease of the corpuscular elements. Preceding the œstrum, as well as menstruation, the opposite condition exists, the corpuscular element increases while the fibrillar decreases or is stationary. We have seen this strikingly exemplified in the deer family.

In women the menstrual flow is preceded by the endo-

Fig. 2.—Endometrium of Woman, Aged Twenty-two. Had never menstruated.

metrium passing through a preparatory stage differing in degree only from the hyaloid condition antecedent to the formation of the placenta. Again we are indebted to Johnstone, for he suggested the term hyaloid used in this connection and pointed out the striking analogy between the histological changes preceding the formation of the placenta and the changes which result in the transformation of osteoblasts into the hyaloid condition in the formation of bone. In this connection we cannot refrain from referring to the interesting experiments of Tinzoni and Fileti in determining the regenerative capacity of glandular tissue, for the process they have observed in the repair of glands like the spleen seems to be similar to

the process that takes place in the endometric changes preceding menstruation. Figs. 2 and 3 are taken from the fresh sections of the endometria of two women, aged twenty-two and twenty five respectively, neither of whom had ever menstruated. The fibrillar character of both sections is marked, and they resemble an infant's endometrium. Compare with these sections one from the endometrium of a woman who had menstruated regularly, and who, at time of death, was thirty years of age.

FIG. 3.—Endometrium of Woman, Aged Twenty-five. Had never menstruated.

The comparative abundance of the fibrillar, in Figs. 2 and 3, over the corpuscular development shown in Fig. 4 is very noticeable. From the absence of the granular character of the fibres and of corpuscular development, we would be justified in calling Figs. 2 and 3 "infantile."

When we study the endometrium as an adenoid structure we can define with far more exactness than has hitherto been done its relation to menstruation. As Johnstone has shown, the menstrual flow prepares the endometrium for the reception of the ovum just as the œstrum with its attendant increases in the lymphatic circulation

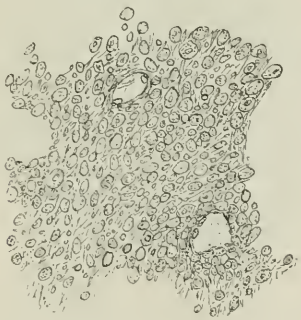

FIG. 4.—Endometrium of Woman, Aged Thirty. Menstruation regular.

does in the lower animals. A normal impregnated ovum may reach the uterine cavity, but if the endometrium has not been prepared for its reception, but has retained its infantile fibrillar character, the ovum will not become attached and will die. The fact that the menstrual flow in women replaces the increased lymphatic circulation of the lower animals is not the sole point of dissimilarity in comparative sexual physiology. We cannot longer introduce "the erect posture" as a distinguishing feature to account for the differences between menstruation and the œstrum. The "erect posture" has done its service for comparative anatomy and physiology as well as for sociology and ethics. Everything that distinguishes man from the lower animals has been accounted for by the "erect posture." We are not without warrant, both from anatomy and physiology, in putting something more into the scale of differentiation between menstruation and the œstrum, and that something is the nervous system as developed in the human subject. Nature has been most lavish in the nerve-supply of the human uterus as compared with that of the lower animals. It is interesting to note that only that portion of the sexual tract which loses its epithelium during menstruation, that covering the body and fundus, is supplied by the sympathetic. The fine nerve fibres follow the helicoid arteries, and in this perhaps we may find an explanation of those functional cases of amenorrhœa which are apparently without cause and often unattended by other symptoms than the simple absence of the menstrual flow. It would be out of the limits of this paper, however, to refer to pathological conditions except so far as they throw light on the anatomy and physiology of the endometrium.

That the functions of the endometrium are governed by automatic ganglia in the uterus itself has received confirmation in a most interesting series of researches conducted by Dr. Robinson. We observed some of the same rhythmic changes in the uterus of a woman which had been removed by abdominal hysterectomy that Dr. Robinson saw in the cow's uterus, changes which seem to be analogous to the rhythmic movements of the heart due to Bidder's and Remak's ganglia. These movements, by their cyclic or rhythmic character, were quite distinct from muscular contractions due to purely physical causes. It is well known that such movements occur in the pregnant uterus, but we do not know of their having been noted in the non-gravid organ.

To recapitulate, then, we have endeavored, 1, to show the dissimilarity between menstruation and the rut—structural as well as functional differences; 2, to emphasize the adenoid character of the endometrium; and 3, to substitute for "the erect posture" as a factor in menstrual physiology the agency of the nervous system with its complex supply from spinal, sympathetic, and ganglionic sources. Recent investigation to prove that the agency of the nervous system has been somewhat underestimated in its effect in governing the menstrual flow, for troubles dependent upon its control, are not as uncommon as were once supposed among primitive peoples, as the American Indian or some of the African tribes.

Why Helmholtz Studied Medicine.—In the course of his speech at the "Commers" given in his honor recently, Helmholtz related how he was gradually led up to the study of medicine as a sort of last resort. "I was," he said "a nervous, sickly boy. I was thirsty for knowledge, but I was handicapped by a shockingly bad memory. For philology and history I was incapacitated by this defect. I liked geometry and could remember it, because it was a logical whole, but yet I had a longing for something more real. Then I came to physics, which I liked, but physics was then a poverty-stricken science, so I had to give it up; and so I was brought eventually to the study of medicine."

The Tenement-House Inspection by the New York Sanitary Police, completed November 1st, shows 38,358 tenement- and smaller apartment-houses, of which 2,391 are rear houses. They contain 276,565 families, embracing 1,225,411 individuals, of whom 160,708 are children under five years of age. The larger apartment-houses, or family hotels, not included in this enumeration, amount to 149, and contain 2,476 families, embracing 9,793 individuals.

A Generous Bequest.—Professor C. Wedl, the well-known histologist of Vienna, who died recently, has left the whole of his estate, amounting to 100,000 florins, to the Mathematico-Physical Section of the Vienna Academy of Science, of which he had been a corresponding member since 1849.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, December 26, 1891.

AN IMPORTANT DECISION.

IN 1885 a Mr. Hartt, who had been a patient at the New York Hospital, brought suit against that institution for alleged ill result following an operation performed upon him by Dr. W. T. Bull, one of the surgeons to the hospital. This suit was tried before Judge Barnard and a jury at White Plains, the question being as to whether the surgeon had performed the operation skilfully or not. A verdict was rendered in favor of the hospital.

During the past year the plaintiff brought another suit, on the same grounds, against Dr. Bull. This suit came before Judge Morgan J. O'Brien, last week, the defendant's counsel, Mr. Austen G. Fox, putting in the plea that as the suit had already been brought against the hospital, and had failed, the plaintiff had no standing in court, his case having been finally disposed of.

In this view the Judge concurred, rendering the following decision :

"It seems to me that, upon the facts as they are now presented, the action made by counsel for the defendant for a direction of a verdict in his favor should be granted.

"The action was originally brought against the New York Hospital for the alleged negligence of one of its doctors. The question then at issue was fairly and fully presented during the trial of the case as to the negligence of the doctor, and upon that there has been an adjudication in favor of the hospital.

"It seems to me upon every principle that it is in the interest of justice, and in accordance with public policy, that after a man has had his day in court, and has been granted and accorded every opportunity of fully and fairly presenting his case, and after he has made his election and tried his case, that he should not be allowed to come in court and try the same question over again.

"Concededly, the liability of the hospital in that case, if it was a liability at all, was a derivative one, being a legal liability resulting from the fact that it had connected with this hospital this doctor, the defendant in this case, no matter on what theory, whether upon the doctrine of election, or whether privy or party to the act or not.

"Besides, putting the matter on the broad ground of public policy, the whole purpose and policy of the law is to put an end to litigation, and this is one of the cases to which that principle should be applied, namely, that when once a man has had his day in court, and had an opportunity of fully and fairly presenting the question at issue, he should not be allowed a second trial for the purpose of presenting the same question to the consideration of the jury.

"The question is a new one in this State. It has been passed upon in other States, but the precise question has not been passed upon here.

"I will direct a verdict for the defendant and require the exceptions to be heard in the first instance at General Term."

Let us see what might result in case a different view had been taken. Given a case in which, during the absence of the regularly appointed surgeon to a hospital, and the tenancy of a *locum tenens*, an operation is performed by one of the house-surgeon's assistants with unfavorable result.

The patient brings suit against the hospital corporation, and failing, sues the attending surgeon. Unsuccessful in this, he sues the *locum tenens* as representative of the surgeon. Then, in turn, the house-surgeon and the latter's assistant.

The same case would go before successive juries, each time upon the same merits, but with a different defendant. The inconvenience and expense at which the hospital and its surgeons would be placed can well be imagined.

It is a principle in law that in failure of an action against the master for the act of a servant the same suit cannot be brought against the servant. Judge O'Brien, in his decision, looks upon the hospital as the master, and its medical officers as its servants. The man who pleads malpractice must elect whom he will proceed against, and must abide by the result of that trial.

THE KAISERBRUNN OF TÖLZKRANKENHEIL, AND HOW IT WAS MADE.

THE cable brings an amusing tale, which is at least *ben trovato*, from Germany concerning a quick-witted scamp who turned to his own advantage the passion of his countrymen for mineral-water cures of one kind and another. The man was a civil engineer, and one day, when jobs were getting scarce, he conceived the truly brilliant idea of affording relief to suffering humanity by means of an iodine mineral water. There have been philanthropists of the same sort long before this ingenious gentleman came upon the scene, but they simply mixed up a lot of more or less poisonous or inert drugs and put them up in variously labelled packages wrapped up in clergymen's certificates. That is good enough in its way, and is often as profitable for the maker of the nostrum as it is injurious to the taker thereof. Some even go further and present each suffering purchaser of their compound chromos of rollicking babies or of placid and healthy-looking nonagenarians. But this benevolent thaumaturgist would have nothing to do with art, for nature was his hold. His customers should feast their eyes on nature and drink only nature's remedy.

And this is how he did it. He purchased a tract of land in the town of Tölz, on the Tzar River, twenty-five

miles from Munich, and already blessed with some wonderful healing springs. Through this territory ran a small stream, which the engineer dammed up and then conducted through a hidden tunnel. At its point of issue he constructed a deep well, filled it with rocks and allowed the water to bubble up, giving it the appearance of a natural spring. The water he treated freely with chemicals, announced the discovery of a new iodine spring, got favorable opinions from experts, and advertised extensively in the papers.

The new spring was loyally christened the Kaiserbrunn, and a company was formed, with the discoverer, or rather creator, at its head to exploit it. The fraud was a success from the start. Capital poured in and a brand new Kursaal with its dependent villas was built. The Kaiser was fast becoming a formidable rival of the older springs. It was visited by thousands of invalids who thirsted for iodine and wanted it good, and the water was bottled and sent all over Europe. The thing was a grand success, and the promoter and everybody connected with him were rapidly growing rich, when the whole business was spoiled by one foolish director. His suspicions were somehow aroused that all was not just as a strictly honest man would like to have it, and so he determined to search for the truth, where it may sometimes be found—at the bottom of a well.

And then came the end, for the investigation which was instituted promptly exposed the origin and the character of the alleged spring. The waters still bubbled up, but the bubble had burst.

The question presents itself, Why should that particular spring be abandoned? The patients who had drank the water, and bathed in it, and recovered their health by dieting and rest, were doubtless just as much benefited as they would have been had the water been naturally impregnated with iodine. Why should their successors be denied this means of recovery just because the water of this spring received its mineral constituents a little nearer the surface of the earth than is usual? This is an interesting world and man is an entertaining study. We all like oleomargarine as long as we believe it to be pure dairy butter.

THE WIDER USE OF LOCAL ANÆSTHESIA.

Dr. C. Scleich, of Berlin, has recently put in a plea for the more extensive use of local anæsthesia in surgery, and as illustrative of its possibilities has reported five laparotomies done under cocaine. Dr. Scleich lays stress on the utility of weak solutions. His laparotomies were done with one-fifth of one per cent. solution of the drug. He states that the maximum amount of cocaine that can be safely injected is one and one-half grain. In cases in which the skin is inflamed the surface is first benumbed with an ether spray. Since June last Dr. Scleich has performed two hundred and twenty four operations under local anæsthesia, without any toxic symptoms being produced. Mention is made of the fact that water and various substances other than cocaine will cause local anæsthesia when injected hypodermically. Thus a thirty per cent. solution of sugar, as well as a one per cent. solution of methyl violet causes endermically complete anæsthesia, and in the same way a two per cent. solution of potassium bromide, a two per cent. solution of caffeine, and a 0.1 per cent. solution of morphia acted as marked anæsthetics. He thinks it the duty of surgeons generally to make use of local anæsthesia in place of general narcosis wherever it is practicable, and he urges his colleagues to subject his method to a rigorous test, for the more perfect the technique of the method the more perfect and free from objection will be the results.

CIGARETTES.

The cigarette industry of this country has for some time been in the hands of a syndicate or trust which now controls the manufacture of about ninety-seven per cent. of all American cigarettes. The total yearly output of cigarettes, according to a writer in *The Sun*, is now about two hundred and forty billions. This gives about eight thousand a year to each of the male population; but naturally a good many are exported. There have been many attempts made to prevent the use of cigarettes by minors, and laws for this end have been enacted in thirty States already. But they are, it is said, ineffective, especially in cities.

A great deal has been charged to the cigarette unjustly. It has been asserted that it causes insanity, consumption, premature death, etc. It is very unwise to attempt to create exaggerated views of an evil concerning which the plain facts are bad enough. These facts are sufficient, and on these alone public educators ought to dwell. Cigarette-smoking is injurious to boys; and inhaling the smoke is injurious to persons of all ages. These two facts ought to be fully known and appreciated, especially by parents and teachers. It is a reproach to the latter class that at present one of the first things learned at boys' schools is to smoke cigarettes.

The practice of inhaling is, as we have before stated in these columns, very widespread and extremely pernicious. Cigarettes can be smoked by adults with as much impunity as cigars or pipes, if the smoke is not drawn into the lungs.

The Austrian Medical Chamber.—A new council, to be called the *Aerztekammer*, has been established by Act of Parliament in Austria. It will examine the character and conduct of its members, expunging names after sufficient testimony; it will also regulate the fees of medical men and lay down laws for the profession respecting benefit societies, insurance examinations, etc. Different medical societies have been endeavoring to have such a council created for the last twenty years.

The Influenza in Germany.—Professor Leyden and Dr. Guttmann have issued the following appeal to their professional brethren: "The report of the committee appointed by the Society for Internal Medicine to collect information concerning the influenza pandemic of 1889–90 is already in the printer's hands, and will be published very soon. As a new influenza epidemic is raging in various districts with great virulence, and it seems desirable to supplement the report with information regarding the time and place of its appearance, the character of the present epidemic, its duration, etc., our professional brethren are urgently requested to support the endeavors of the committee to the best of their ability by sending us short communications on these points."

News of the Week.

The Jenkins Medical Society, of Westchester County, N. Y., celebrated its twenty-fifth anniversary at the Yonkers Club House, Yonkers, N. Y., Monday evening, December 21st. There was a large attendance of members and invited guests, and the occasion was an enjoyable one. The Society was named in honor of the late Foster Jenkins, of Yonkers, who was a leading practitioner of Westchester, a distinguished sanitarian, and ex-President of the Medical Society of the State of New York.

The Students at the University of Moscow are said to be on the eve of one of their periodical outbreaks and are consequently under constant surveillance by the police. Among one of the curious rules laid down by the authorities is that no more than seventy students shall be allowed to attend any single theatre the same evening. Numbered tickets are sold to the students at the box-office, and each purchaser must give his name and furnish other means of identification, so that in case of disturbance the authorities will know who were concerned in it.

He Wants His Body Back.—A man in Massachusetts was very hard up some twenty years ago, and was glad to sell his body, to be delivered at death, for ten dollars. Since then, however, he has made a comfortable fortune, and now wants to buy back the deed of his body. The former purchaser is reluctant to sell for any small amount, holding off for a rise, and it is now only a question of how much the man thinks his corpse will be worth.

Yellow Fever is raging in Santos and Rio Janeiro, and nearly every vessel that returns to this port from Brazil is detained at the Quarantine station for disinfection. The Advance, which arrived on Monday of this week, had had four deaths from yellow fever on the voyage, and seven persons sick with the disease had been sent ashore at Bahia. The officers of the steamer say that they have never seen so severe an epidemic as that now raging, the recently arrived immigrants being those chiefly affected. Of these, it is said that many die in the streets uncared for, and that scarcely one has escaped.

The Association of Military Surgeons of the National Guard of the United States.—The second annual session of this Association will be held at St. Louis, April 19, 20, and 21, 1892. An interesting programme of addresses by surgeons of the National Guard and the United States army has been arranged; a number of scientific papers on military and accidental surgery will be read and discussed, and all matters pertaining to the health, usefulness, and welfare of the civilian soldiers will receive attention.

Montreal Medico-Chirurgical Society.—At the annual meeting of this Society, held on October 23d, the following officers were elected for the term 1891–92: *President*, F. Buller, M.D.; *First Vice-President*, James Stewart, M.D.; *Second Vice-President*, E. P. Lachapelle, M.D.; *Treasurer*, J. A. McDonald, M.D.; *Librarian*, T. D. Reed, M.D.; *Secretary*, Kenneth Cameron, B.A., M.D.; *Council*, James Perrigo, M.D., Wesley Mills, M.D., James Bell, M.D.

A Hypnotizer in Jail.—A man, calling himself Dr. Vint, has been sentenced to three months at hard labor in England, for giving exhibitions of alleged hypnotism. It seems that there is a law there to punish anyone who pretends to tell fortunes, or to deceive or impose upon any of her Majesty's subjects.

Dr. J. Howard Tracy, formerly of Honesdale, Pa., died recently at Escanaba, Mich., aged forty seven years.

Worshipping the Bottles.—A story is told in the *Nursing Record* concerning the touching conversion of some Burmese. A zealous well-known lady missionary, in one of her tours, came to a village where cholera was raging. She had a number of bottles of a "noted pain-killer" with her, which she apparently dispensed with great liberality to the stricken villagers, and, leaving a further supply for future use, went on her way. Some months afterward she returned to the same village, and was met by the head man with the following gratifying announcement: "Teacher, we have come over to your side; the medicine did us so much good that we have accepted your religion." The highly delighted missionary followed the man to his house, and there in an inner room she beheld a stately row of the pain-killer bottles ranged solemnly on a shelf, and before these all present—saving, presumably, the missionary—prostrated themselves in worship. The story ends there, and is not spoiled by any account of the good lady's efforts to disentangle the simple but logical ideas of cause and effect in her new converts' minds.

A Hospital for Convalescent Phthisis Cases is to be erected by the Berlin authorities on the outskirts of the city.

A Very Young Woman.—Dr. Overstreet, of Live Oak, Fla., writes to the *Atlanta Medical and Surgical Journal*: "We have a little girl in this county four years old who is a fully developed woman in every respect, and was that way at two years and nine months. Can this be excelled in any land or country?" She ought to meet the Indiana prodigy, a boy of six, who gives lectures on anatomy.

Dr. Samuel C. Robinson, of Brooklyn, died on December 25th, aged sixty-two.

Dr. Roswell Park Collin, of this city, died on December 21st, after a protracted illness. He was thirty-nine years old.

Syphilis in Paris.—At the close of the World's Fair at Paris it is stated that that city had within its limits 50,000 women with syphilis.

Scandinavian and German Morality.—Professor Saved Ribbing, of the University of Lund, some time ago gave the association of students a series of three lectures on sexual hygienic laws and their results. These lectures were subsequently published in a pamphlet, which has just been translated into German by Dr. Oscar Reyher. The reviewer in the *Medicinische-Chirurgische Rundschau* protests against an observation of the translator, to the effect that most of the descriptions of Professor Ribbing are equally applicable to Germans. In his opinion the

erotic instinct is much less developed in the young people of Germany than in those of other nations. Even in Scandinavia the increase of sexual excesses seems to be of recent occurrence, and is due to circumstances the proper appreciation of which is difficult for those at a distance.

Another Heart Tonic, resembling digitalis, is the tincture of coronilla varia, recommended by Dr. Poulet, of Planches-les-Mines; and tincture of coronilla scorpioides, recommended by MM. Spillmann and Haushalter.

The Death of Professor E. Bouchut, of the Medical Faculty of Paris, is announced.

Compulsory Vaccination and Revaccination in Italy.—A new vaccination law will come into operation in Italy on January 1, 1892. Arrangements are made under it for the cultivation and supply both of humanized and of animal lymph. All children except those who have already had small-pox, or who are medically certified to be in ill health, must be vaccinated within the solar half-year subsequent to the date of their birth; and where renewal of any such certificate of unfitness is in question, the child must be inspected by the official vaccinator, with whom the final decision will rest.

Is Dentistry a Dangerous Profession?—Dr. Buxton, in the *Dental Record*, asserts that dentists suffer to an unusual degree from neurasthenia, nervous debility, migraine, sciatica, herpes zoster, insomnia, etc. He attributes this to confinement, over-work, and bad air.

The Contributions to the London Hospitals have been $350,000 less than usual during the past year. This is thought to be due partly to the charges of mismanagement, partly to the demands made on philanthropic people by General Booth.

The Influenza in New York City, in 1891, showed itself about the middle of last March and began to decline in the middle of April, but lasted into June. It raised the death-rate but slightly. It reappeared in this city about the middle of October. Since then two or three deaths per week from influenza were reported, but no increase of weekly death-rate has been noticeable, at least up to a week ago. The average weekly death-rate of the city is about seven hundred. During the height of the epidemic of 1889–91 the death-rate for one week was 1,424.

Doctors in the Legislature.—"In no European legislature," says *The Lancet*, "are there so many distinguished surgeons and physicians as in that of Italy. One of the best of her best prime ministers was the 'general practitioner' of Casella in Piedmont, Giovanni Lanza, under whose wise and well-timed policy she transferred her capital from Florence to Rome, while statesmen of Cabinet rank in nearly every administration have been drawn from her men of light and leading in medicine, prominent among whom may be mentioned one of her ablest Ministers of Public Instruction, Dr. Guido Baccelli. Nearly every year she adds to the number of her senators one or more of her chief professors of the healing art, the latest accession to these 'Patres Conscripti' being Dr. Enrico Bottini, who holds the Chair of Obstetrics at Novara. Professor Bottini was for some time Lecturer in Clinical Medicine at the University of Pavia, where he gave such proof of general as well as special ability that he was elected Deputy to the Italian Chamber. From there he has been raised to the senate."

The Influenza is present in certain parts of England and Scotland, Berlin, Poland, St. Petersburg, Hamburg, Bordeaux and some other widely scattered areas. It is said to be present in some cities of this country, and to be developing in this city.

The Ohio State University Trustees are carefully considering the advisability of establishing a medical department. That a medical department will somehow be organized, in the near future, seems very certain.—*Columbus Medical Journal.*

An Interesting and Instructive Malpractice Suit was recently terminated in the Philadelphia courts (*Medical News*). On March 15, 1889, the plaintiff visited a market in West Philadelphia, and, accidentally stepping on a knife, the point was thrust through the tendo Achillis. She immediately summoned Dr. A. F. Chase, who, finding a narrow punctured wound with but little separation in the tendon, and no bleeding, carefully dressed the parts, with the foot extended so as to relax the gastrocnemius. The wound healed, with evidence of separation of the tendon of about a quarter of an inch. The butcher before whose stall the accident happened was anxious to make all reasonable amends, but the plaintiff could not be satisfied, and brought a suit against him. Before the suit could be brought to trial he sold out his business and left for parts unknown The plaintiff then consulted her lawyer with reference to bringing suit against the market company. This he assured her would be useless, and, finding that suit was to be brought against the attending physician, the lawyer gave up the case. About this time the plaintiff, desirous of getting outside medical testimony, engaged a carriage, was driven to a well-known hospital, was carried tenderly into the "out" surgical department, and, after the examination, was again carried tenderly back to her carriage, having, as she thought, gained some important medical testimony as to what would have been proper treatment of the original injury. She also engaged the hospital surgeon to attend her at her home. Unfortunately for her, but quite the reverse for the defence, it was observed that in the evening of the same day the plaintiff was seen to leave her home and walk to a neighbor's, apparently as if nothing had happened to her. Fortified with additional medical testimony, counsel was again employed, and action brought against Dr. Chase, in March, 1890. The trial was postponed, however, and finally the plaintiff was non-suited.

The Plague is reported to have broken out in the Government of Kazan, in Russia, among the famine-stricken peasantry.

An Elderly Mother.—Dr. Derasse, of Liege, recently attended a woman in confinement who gave birth to a bouncing boy when she was fifty-nine years and five months old.

Practice was Dull.—Two burglars, who were recently caught trying to blow open a bank safe in an Illinois village, were found to be the village physicians, and now there is an opening in the place for an honest doctor.

Society Reports.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, June 10, 1891.

H. M. Biggs, M.D., President, in the Chair.

Calculous Pyelo-nephritis.—Dr. H. J. Boldt presented a specimen of this condition, and it was particularly interesting on account of its clinical features. The patient had come to him for an operation on a vesico-vaginal fistula, and previous to the operation had given no history, or presented any symptoms referable to the kidneys. There was no pus in the bladder or coming through the fistula, and as the existence of the fistula made it necessary, in order to secure accurate results in an examination of the urine, that the ureters be catheterized, it was thought safe to omit this examination. The patient was under ether about half an hour. Three or four days after the operation she died, with all the symptoms of renal disease. Owing to the constant dribbling away of the urine the bladder was extremely small, and its elasticity destroyed. The opening of the ureters was easily seen, and there was no constriction of either ureter. The right ureter contained considerable pus. The right kidney was large, the mucous membrane of its pelvis was congested, and this cavity was filled with pus. A stone of considerable size was found here. Scattered through the kidney were small abscesses, and considerable portions of kidney tissue had been destroyed. The left kidney was somewhat smaller, but presented much the same appearance, except that gravel took the place of the stone.

Dr. J. H. Linsley said that the unfortunate termination of the case just reported made it seem desirable to insist once more upon the frequency with which nephritis is developed after an etherization. Several cases had come under his observation in which careful examinations of the urine at intervals, for a period of six months before an operation, had been absolutely negative, and yet after a rather prolonged administration of ether a nephritis was promptly established; in fact, even before the completion of the operation the first indications of this condition, hiccoughs, were present. In these cases the urine showed the usual characteristics of this condition—all the varieties of casts, granular degeneration, and fatty globules—and the post-mortem examination still further confirmed the diagnosis.

Dr. H. J. Boldt also presented a uterus which he had removed from a patient by vaginal hysterectomy. The patient, a married woman, thirty-three years of age, had had one child, and no miscarriages or abortions. For eight years previous to coming under his care she had been suffering from intense pains in the ovarian and lumbar regions, increasing in severity with menstruation, which was irregular and very profuse. A small ovarian cyst was removed from the right side by laparotomy. The after-treatment consisted in the use of various hygienic measures, the administration of hydrastis canadensis and of tonics internally, and locally, in intra-uterine positive galvanization, and the introduction of tampons. Although temporarily improved, she soon began again to suffer from severe pain and profuse uterine hemorrhages, and these not proving amenable to treatment, a second laparotomy was undertaken. The operation was rendered quite difficult by the existence of extensive and firm adhesions. There was a pyo salpinx of the left tube, and a hæmatoma of the ovary. She was not improved by this operation, but, on the contrary, began to suffer not only from pain, but from most obstinate and distressing nausea and vomiting, and her general nutrition was rapidly and seriously impaired. All ordinary treatment seemed unavailing, and although her condition was so critical that it was thought she would die from the shock of another operation, such a procedure was decided to be the last, although certainly a dangerous, resort. It being evident that the uterus was the seat of the trouble, this organ was removed by vaginal hysterectomy. As was expected, the extensive adhesions to the omentum and intestines made this operation one of great difficulty, as well as gravity; but fortunately the patient rallied, and during the week which had elapsed since this operation was performed, there had been no return of the previous symptoms, and she now appears to be convalescing favorably. A microscopical examination of the specimen showed the case to be one of glandular endometritis and chronic metritis.

The speaker added that the case was one of more than usual clinical interest, inasmuch as this was the first one on record in this country in which a chronic metritis had caused such a complex and serious condition, and had not only caused the patient endless suffering, but had actually jeopardized her life. Although the treatment was radical, and at first sight seemed hardly justifiable, the result had proved the wisdom of the treatment adopted.

Dr. W. P. Northrup presented a card specimen showing a very remarkable tearing up of the lung in a baby of two months, as a result of an interstitial emphysema produced by severe whooping-cough. The section was taken from the right upper lobe, and the whole of this lobe was a honeycombed mass, while the middle and lower lobes were simply pneumonic. The left lung contained nothing worthy of note, except a small amount of emphysema. The speaker said this was the only specimen of its kind which he had met with out of hundreds of autopsies upon children.

Tuberculosis of Ovaries and Tubes.—Dr. H. P. Loomis presented gross and microscopical specimens of this condition. The ovaries and tubes had been removed by Dr. Polk and sent to him for examination. The patient, who was twenty-seven years of age, had enjoyed good health up to six months previous, when she began to suffer from abdominal pains, and after being curetted by some physician, a pelvic peritonitis developed. When seen by the speaker, three weeks after the laparotomy, there was nothing to indicate pulmonary tuberculosis, and Dr. Polk assured him that there were no indications of this disease about the pelvic organs. There was no ascites.

The specimen was seen to be made up of dense fibrous tissue, and contained small cavities filled with cheesy material. The tubes were dilated to the size of the forefinger, and contained the same material. The microscope showed areas of coagulation necrosis, surrounded by broad bands of connective tissue, which contained numerous giant-cells. No tubercle bacilli had been found in the sections.

Dr. Loomis considered that many cases diagnosticated as purulent ovaritis were really instances of tuberculosis of the ovary.

Dr. Boldt said that he had seen a number of such cases, and in every case of tuberculosis of the uterine appendages ascites had been present.

The President said that nearly all the cases which he had observed had been associated with tuberculosis of the uterus, and Italian observers had succeeded in finding the tubercle bacilli in the uterine discharges. There had been no ascites in his cases. Quite recently he had seen a case very similar to the one just presented, except that it was not so extensive. The operator, Dr. Lusk, had questioned his diagnosis of tuberculosis of the tubes and ovaries, but shortly afterward the patient developed a tubercular peritonitis, and died.

Dr. H. P. Loomis also exhibited a lung which presented a somewhat puzzling condition. While there was no positive evidence of its being tubercular, he was of the opinion that it was probably an instance of cured miliary tuberculosis. There was no history. At the autopsy the left lung was found compressed against the vertebral column, and the left pleural cavity was filled with sero fibrinous fluid. The other lung showed advanced tuberculosis, and contained a cavity at its apex. The left lung was solid, and contained no air, and the

pleura was thickened. On section, the whole surface of this lung was found studded with small nodules, the upper lobe being converted into a solid mass of dense, firm, fibrous tissue, of a slaty color. The speaker presented some microscopical specimens taken from two different portions of this lung. They showed these nodules in the centre, undergoing coagulation necrosis, and around these were bands of connective tissue with pigmented deposits in the outer zones of this tissue. Between these nodules were compressed air-cells, with much fibrous tissue in their walls.

The speaker said that he could recall at least two cases in which tuberculosis had ceased to advance as soon as the pleural cavity had become filled with fluid, and he thought that the shutting off of the air from the lung, while the circulation continued, might have been sufficient to excite a connective-tissue hyperplasia, which would limit these nodules and prevent a further extension of the tuberculous process.

DR. NORTHRUP called attention to the fact that some of the small bronchial lymph-nodes were very dark-colored.

THE PRESIDENT was of the opinion that the specimen was an example of "miners' phthisis," or anthracosis, associated with compression of the lung from the pleural effusion. He could not recall any case, however, in which there was such an extensive fibrous formation around the nodules. He suggested that sections from other portions of the lung be subjected to examination, and the result reported to the Society at some future meeting.

The Society then adjourned.

Correspondence.

A DANGEROUS MATERNAL IMPRESSION.

To the Editor of the Medical Record.

SIR: It is a strange thing how the subject of "Maternal Impression" seems to have taken hold of medical literature. Wherever one looks he finds an article on "Maternal Impression." Will you allow me to communicate a case which has fallen under my own observation. You will find it a rather singular one, and difficult of belief, but I vouch solemnly for the truth of it. There is a little place in the State of Missouri, which, as my story is true, I will not call by its own name, but by that of Abdera. Thither came, some years ago, a young physician, good-looking, of fine address, *l'oreille rouge et le teint fleuri*. He was soon a favorite and an oracle in some of the best families. In due time it happened that a number of children all over the city were found to be strikingly like in features to this young Æsculapius You can easily fancy the talk which arose; even the benevolent in secret shook their heads and meditated. But soon unexpected light was thrown upon the matter. There came a private lecturer—a lady—who explained to her feminine audience—she lectured only to ladies—that oftentimes even the careful and modest ministrations of a much-esteemed physician produce on the maternal mind an impression materially transmitted to the unborn offspring. This solution was adopted, and great relief was experienced in consequence.

NON JUDÆUS APELLA.

THE PHYSIOLOGICAL RELATION OF ALCOHOL TO FOOD.

To the Editor of the Medical Record.

SIR: Under this heading, in the issue of the MEDICAL RECORD dated December 12, 1891, attention is called to Table VII., which appeared in my original article having the above title. Table VII. is spoken of as "at least remarkable," and its authenticity somewhat called in question.

In reply I would say that Table VII., as found in my original article in the 17th of October issue of the MEDICAL RECORD, was taken from Professor John C. Dalton's "Human Physiology for Students and Practitioners," sixth edition, 1875, p. 127. Philadelphia: Henry C. Lea.

Further in reply I wish to say that the "laws of nature," as referred to in my original article, are chemical and physiological phenomena which govern the human economy.

These phenomena are carefully studied in clinical practice, and when fully recognized justify the formulation of a theory, and when an applied theory uniformly disperses symptoms, changes the abnormal and by-products in the urine to the normal excrementitious substances, I hold we are further justified in asserting the existence of a natural law.

WILLIAM HENRY PORTER, M.D.

FIVE AT A BIRTH.

To the Editor of the Medical Record.

SIR: In your esteemed journal of December 12th is an inquiry for any record of an American woman giving birth to five children at one confinement. In 1882, while practising at Findlay, O., a case came to my knowledge of a quintuplet birth, three of the progeny breathing but a short time, and the other two surviving some months. This case occurred at the County Poor Farm, and the husband of the woman was at the time classed as "totally disabled," on the Government pension rolls, being nearly doubled from rheumatism.

GEORGE C. MOSHER, M.D.

KANSAS CITY, MO.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 19, 1891.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	27	5
Scarlet fever	175	33
Cerebro-spinal meningitis	4	4
Measles	126	17
Diphtheria	149	39
Small-pox	0	0
Varicella	2	0
Pertussis	0	4
Erysipelas	2	0
Mumps	0	0
Rötheln	0	0

A Persistent Lady Doctor.—A conflict has been going on for some time past between the authorities of the Department of the Seine and a lady named Schicklé, who is practising as a physician at Billancourt under the name of "Dr. Verneuil." Proceedings were taken against her, on the instigation of the local doctors, and she was fined five hundred francs. She paid the fine and calmly resumed her consultations. Fresh complaints were made, and a fresh summons was issued against her. She tore up the paper and sent the pieces back to the Public Prosecutor. She also wrote letters to various authorities, stating that she had passed examinations in the nervous and mental disorders of women, and was greatly complimented on her knowledge. Several attempts have been made to arrest her, but hitherto they have been fruitless. She is greatly liked and protected by the inhabitants of the district, and they have invariably prevented the police from getting at her. What will be the ultimate issue it is impossible to say.

The Parasite of Irregular Malarial Fevers.—Dr. M. W. Sakharoff (*Ann. de l'Inst. Pasteur*, July 25, 1891) has a note on certain parasites occurring in the blood of patients suffering from irregular malarial attacks. These are different from those found in the "regular" fevers, being small, pale bodies enclosed in the blood-corpuscles, endowed with amœboid movements, and assuming a round shape when at rest. In course of development this amœboid condition undergoes the following modifications: Pigment granules appear, mobility is gradually lost, and the form becomes round. The granules unite into a mass at one side or in the middle of the parasite, and a nucleus previously visible can be no longer seen. During this time the parasite increases in size, but always remains smaller than the blood-corpuscle, of which a large portion is unoccupied. After a time fission commences, and this may be observed in blood drawn from the finger (the parasite described by Marchiafava in connection with regular malaria only divides in the internal organs and not in shed blood). This fission takes place in the interior of the corpuscles, after which the segments, from four to sixteen in number, escape, and either remain free or become enclosed in leucocytes. In these latter further development very rarely occurs. This is the normal life-history, but two modifications may be at times observed: 1. Sometimes the course is more rapid, and fission begins before pigment formation. 2. At other times new crescentic forms appear, and the disease assumes a chronic course. This is a highly interesting form, and one about which there has been some controversy. The author believes (1) that in cases in which these occur the fever seldom assumes a recurrent form. He considers (2) that usually these crescentic bodies are not developed, although at the commencement the amœboid parasites may be present in enormous numbers. He states also (3) that these crescentic bodies may be found in the blood of patients suffering from an irregular attack, but are very seldom seen in the course of a regular malaria. These crescents change gradually into oval or round bodies. Generally also, as the author has proved by actual observation, some of these round bodies develop a number of motile filaments, at least in preparations outside the body; finally they disappear and leave no trace. Attempts to cultivate the parasites have all failed. Fowls also showed themselves insusceptible, and the parasite has not been found in their blood, although these are said to suffer from the malaria. In the blood of some geese, however, affected in an extremely malarial district of the Caucasus, the author found a hitherto undescribed spiral parasite. He is making further researches on this parasite.

Handkerchiefs for Consumptives.—Dr. A. Tucker Wise, writing in *The Lancet* of November 14, 1891, advises the use of cheap handkerchiefs dipped in a solution of nitrate of potassium, which offer a cleanly and safe means for the disposal of infectious expectoration where a spittoon is not at hand, as they are burnt after use. Their advantages are: 1. The expectoration is maintained moist for some time by the potassium salt, and cannot blow about as dust. 2. A handkerchief can be rapidly destroyed by throwing it on the fire, or even setting it alight in a grate with a piece of newspaper. 3. The cost is not great, varying of course with the quality of the handkerchief used, and there is nothing unusual in the appearance of the handkerchief. At meal times their use is an obvious convenience. Whatever theory may be held regarding the danger of sputum dust, the writer says, the above method appears to be practical and cleanly, and more likely to be adopted when the cost is about the same as washing.

Leprosy in Japan.—According to the native journals there has been a great increase in the number of lepers in that country in recent years, and considerable alarm is felt on that account.

Where the Big Men Grow.—The *Telegram-Herald* of Grand Rapids says that the tallest men of Western Europe are found in Catalonia, Spain; Normandy, France; Yorkshire, England, and the Ardennes districts of Belgium. Prussia gets her tallest recruits from Schleswig-Holstein, the original home of the irrepressible Anglo-Saxons; Austria from the Tyrolese highlands. In Italy the progress of physical degeneration has extended to the upper Apennines, but the Albanian Turks are still an athletic race, and the natives of the Caucasus are as sinewy and gaunt as in the days of the Argonauts. In the United States the thirty-eighth parallel, ranging through Indiana and Northern Kentucky, is as decidedly the latitude of big men as the forty-second is that of big cities. The tallest men of South America are found in the western provinces of the Argentine Republic, of Asia in Afghanistan and Kaypooana, of Africa in the highlands of Abyssinia.

Cremation.—It will interest cremationists to hear that the Japanese, who some time ago adopted burial of the dead, in imitation of European nations, have reverted to their own custom of burning the dead on account of its sanitary recommendations. That the practice is in a fair way to gain favor in England, appears from the unexpected measure of support given to it at the recent meeting of the British Medical Association. Sir William Moore went as far as to say that "Christian burial" was worse than the Parsee system of exposing bodies to the vultures. Several of the doctors went to what seems an extreme length in describing the insanitary effects of a graveyard in the neighborhood; and one case was cited from India where an outbreak of cholera had occurred through the digging up of an old cemetery in making a railway.—*Indian Medical Gazette.*

Long Fasts in India.—A correspondent of the *Times of India*, referring to recent long fasts in this country, says that in India fasts of thirty to forty days are common among the Jains, from among whom, once in each year, some individual comes forward and undertakes to fast thirty five, forty, and even sixty days. They do this with nothing but warm water to drink, and will die rather than take food during the prescribed period. Quite recently two Jains of Bombay fasted, one for sixty-one the other for forty-eight days, at the end of which time, having been congratulated by twenty-five thousand Jains who went for the purpose, they recommenced taking food in the manner prescribed in their own books and shastras. On September 22d, in commemoration of this event, all the chief bazaars in Bombay were closed, and about five thousand Jains, male and female, fasted all day, while a large sum was spent in securing the release of cows and other animals from the slaughter-house at Bandora.

Suicide in the Armies of Europe.—Dr. Langer has been investigating the subject of suicide among the soldiers in European armies, his statistics including the years from 1875 to 1887. The largest number of suicides occurred in the Austrian army, averaging 122 a year in each 10,000 soldiers. Next to Austria is Germany, which averaged 63 suicides to every 10,000 soldiers. In the Italian army on the average 40 soldiers in every 10,000 committed suicide every year. The French army from 1872 to 1889 lost in Europe 29 soldiers to every 10,000 annually, and in Algeria it lost just twice as many by suicide. In Belgium there occurred 24, in England 23, in Russia 20, and in Spain 14 to every 10,000. The cause of suicide in the army appears in most cases to be the fear of punishment, though not a few are driven to the act through aversion to military service and despair of ever being able to return to civil life.

Dr. E. von Esmarch, son of Professor v. Esmarch, of Kiel, has been appointed Professor of Hygiene in the University of Königsberg, in the room of Professor C. Fränkel, who has gone to Marburg.

INDEX.

A

Abbott, George E., a plea for full mechanical dilatation of the parturient canal before obstetrical or gynecological operations, 648; the old and new iodine bottle, 523; an undescribed disease—posterior rectrocele, 235.
Abdomen, retro-peritoneal tumors, 402.
Abdominal disease, pleural effusion associated with, 751.
Abdominal section, drainage after, 49, 77, 267; the thermometer in, 609; *see* also laparotomy.
Abdominal tumor of uncertain nature, 163; complicated with pregnancy, method of procedure in, 460.
Abernethy, Hugh H., death of, 747.
Abortion, frequency of criminal, 692; habitual, 538; induced, for the relief of nausea and vomiting, 669.
Abscess, detection of, 44; in Pott's disease, 385; psoas, some of the complications of, 668.
Achorn, J. Warren, the new Americans, 329.
Acne, corrosive sublimate for, 553; treatment of, 138.
Actinomycosis, 345, 697.
Addison's disease, pathological anatomy of, 130.
Adenia, simple, or Hodgkin's disease, 455.
Adenoid growths, new forceps for, 166.
Adenoma, papillary, of the kidney, 80.
Adulteration of drugs, 437.
Æsculapius, pæan in honor of, 440.
Air-passages, upper, and their diseases, 709; upper, relation of disturbances of the mucous membrane of the, to constitutional conditions, 416.
Albumin, various tests for, 382.
Albuminuria, functional, 241; in its relation to life insurance, 82; relation of, to surgical operations, 639; salts of strontium in, 636.
Alcohol, benefits of drinking, 671; consumption of, in Germany, 337; effects of, 314; in medical practice, 134, 135; in the etiology of tuberculosis, 278; physiological relation of, to food and its proper use in medicine, 469, 726, 768; use and abuse of, 342.
Allen, Dudley P., drainage in abdominal surgery, 267.
Alopecia areata, 412; new treatment for, 185.
Alumni Association of the Woman's Hospital, 108.
Amaurosis, 406.
Ambulance drill in the National Guard, 306; service in London, 338; system of New York, 156.
Amenorrhœa and dysmenorrhœa, treatment of, by apiol, 183.
Amenorrhœa, relief of functional, 139.
American Association for the Advancement of Science, 243.
American Association of Andrology and Syphilology, 362, 383, 424.
American Association of Obstetricians and Gynecologists, 459; and the Congress of American Physicians and Surgeons, 661.
American Climatological Association, 359, 379, 417.
American Dermatological Association, 356, 376, 411.
American Gynecological Society, 354, 374, 409.
American Laryngological Association, 357, 377, 415.
American Medical Association, representation in the, from New York, 581.
American Neurological Association, 353, 372, 407.
American Ophthalmological Society, 404.
American Orthopedic Association, 364, 384, 427.
American Otological Society, 367.
American Pediatric Society, 366, 387, 433.
American Physiological Society, 365, 386, 430.
American Public Health Association, 587, 693.
American Surgical Association, 351, 370, 399.
American women, physique of, 636.
Amœba coli in dysentery and liver abscess, 7.
Amputation at the hip-joint, 450.
Amputations with regard to artificial legs, 609.
Anæmia, pathology of, 491; pernicious, pathology of, 422.
Anæsthesia, hysterical, pathology of, 372; of fourteen years' duration, disappearance of, after removal of a neuroma, 407; the A. C. E. mixture for, 49; the wider use of local, 764.
Anæsthetic, carbolic acid as a local, 254; nitrous oxide and oxygen as an, 304; water as a local, 306, 613.
Anatomy and physiology of the uterus, some points in the, with special reference to the adenoid character of the endometrium, 760.
Anatomy, papers relating to, read at the third annual meeting of the Association of American Anatomists, 432.
Aneurism of the basilar artery, 518.
Angiomata, meningeal, 538.
Angio-sarcoma, tubular, 79.
Animal diseases, 694.
Animal tissues, therapeutic use of, extracts of, 390.
Annales d'Oculistique, 338.
Antikamnia, death from, 608.
Antipyrin, incompatibles of, 154; rash from, 23.
Antisepsis and disinfection, 194; true surgical, 555; what it has done, 213.
Antiseptic, a new, 601; a new intestinal, 756; and aseptic details in surgery, 370; dissecting cases, 522; operations, preparing the skin for, 255, 588; solutions, cleansing the hands after the use of, 563.
Antiseptics in ophthalmic and aural surgery, 464.
Anus, fissure of the, 311.
Aortic insufficiency, two types of, 455.
Aphthæ, boroglyceride for, 24; thuya for, 347.
Apiol, treatment of amenorrhœa and dysmenorrhœa by, 183.
Apoplexy in Rome, 748.
"Apothecary," a new journal, 306.
Appendicitis, 491; a disease of Americans, 245; in woman, 722; treatment of, 22.
Arachnoid of the brain, 177.
Aristol, 633.
Armies of Europe, suicide in the, 769.
Army news, 28, 56, 84, 112, 140, 167, 196, 224, 284, 348, 467, 494, 523, 554, 585, 644, 672, 700, 727, 756.
Army, report of the surgeon-general of the, 546.
Arnica eruption, 28.
Arnold, Will F., the first hip-joint amputation in America, 81.
Arsenic, in common life, 669; poisoning and wall-papers, 662; poisoning from coal, 244; subcutaneous injection of, 239; value of, 137.
Arterial disease and visceral changes, relations between, 421.
Arteries, changes in, after ligation with tendon ligatures, 25.
Arthritis of obesity, 393; spurious, from nerve-lesions, 553.
Arthur, William H., an unusual case of dislocation by direct violence of costal cartilages unattended with serious consequences, 211.
Ascites, black, 538; pressure, 580.
Aseptic and antiseptic details in surgery, 370.
Aseptic rivers, need of, 486.
Ashmead, A. S., inoculation of a Japanese with scarlet fever germs, 270.
Association of American Anatomists, 432.
Association of American Physicians, 360, 381, 421.
Astasia-abasia, 354.
Asthenopia, accommodative, 407.
Asthma, permanent relief from, following treatment of the upper air-passages, 358.
Astragalus, dislocation of the, 581.
Ataxy, acute, 303.
Athetosis, double, 408.
Atomizing tube, a new aseptic, 283.
Atrophies, a study of, 386.
Atropine, mode of action of, when applied to the cornea, 537.
Auditory centre, lesion locating the, 408.
Aulde, John, treatment of a "bad cold," 671.
Australia, quarantine in, 280.
Austria-Hungary, medical profession in, 737; population of, 338.
Avicenna, proposed monument to, 128.

B

Bacilli in sections of tissue, rapid staining of, 695.
Bacillus coli communis, pathogenic properties, etc., 721; typhosus, detection of, in water, 506.
Back-ache, for the relief of, 553.
Bacteriologists, disagreeing, 688.
Baldness, cause and cure of, 157.
Baldwin, W. E., absence of the rectum, death of the child in fifty-six days, 714.
Barge office physicians, 663.
Barker, Fordyce, memoir of, 625.
Barr, S. Dickson, the extraction of incipient cataract, 712.
Barrows, Charles Clifford, the use of the electro-magnet to extract buried particles of iron or steel from the tissues, 738.
Basilar artery, aneurism of the, 518.
Bath, physical examination in a, 458.
Baths, public, in New York, 243, 573; river, in winter, 4.
Beds, separate, and nervous force, 72.
Beebe, Carl M., the medical practice law in Minnesota, 726.
Beer versus wine, 195.
Bennet, Henry, death of, 222, 440.

Benzoate of naphthol β, 756.
Beri-beri, clinical notes on five cases of, 452.
Berlin, American students in, 394; body-snatching in, 306; letter from, 111.
Bevill, Cheves, the first hip-joint amputation in America, 81, 492.
Bichloride of gold club, 74.
Bicycling as an exercise, 389.
Biliary lithiasis, 636.
Biliary colic, belladonna for, 754; sweet-oil for, 513, 630.
"Biliousness," treatment of, 137.
Billy Patterson, who struck? 672.
Biochemic school of medicine, 48.
Birds as surgeons, 468.
Bladder, distended, how to empty, 588; female digital examination of the, 137; nutmeg for irritability of the, 754; prolapse of the, in an infant, 631; rupture of, surgical treatment of, 383.
Bleeding, therapeutics and physiology of, 17.
Bliss, T. F., a curious case of vision dependent on the use of both eyes, 12.
Blood-current, effects of certain drugs on the velocity of the, 292.
Boils, abortion of, 139; benzine for, 139; treatment of, 601.
Bone, reproduction of, from blood-clot, 163.
Bone-grafting, 133.
Bone-shedder, 188.

Cæsarian section, a case of, 125; the present and improving status of, 356.
Caffeine in pneumonia, 538.
Caisson disease, pathology of the, 141, 178.
Caius, Dr., discovery of the grave of, 615.
Calculi, intestinal, 15.
Calculus, renal, 519; urinary, boro-citrate of magnesium in, 24; urinary, spontaneous expulsion of a large, 510.
California, climate of Southern, for respiratory diseases, 361.
Calomel in eclampsia, 715.
Camphor, hypodermic injection of, 483.
Camphoric acid, 298.
Camphor-menthol in catarrhal diseases, 550.
Canada, five years' medical course in, 46.
Canadian Medical Association, 490.
Cancer. *See* carcinoma.
Cancer-cure, collapse of another, 748.
Cancer-grafting, 160, 338.
Canities unguium, 216.
Cantharidin, 245.
Carbolic acid as a local anæsthetic, 254; in rheumatism, 552.
Carbuncle, 414; chloral hydrate for, 24.
Carcinoma, cause of, 133; colloid secondary to internal, 519; infectiousness of, 281; of the breast, 584; of the breast, recurrence of, 399; of the cervix uteri, results of the high operation for, 374; of the larynx, 416; of the lungs, 257; of the œsophagus, gastrostomy in, 435; of the pancreas, 79; of the stomach, new diagnostic sign of, 690; of the vertebræ simulating Pott's disease, 533; primary, of the broad ligament, 356; proclivity of women to, 606; Stites's test for, 718.
Carious bone, removal of, by hydrochloric acid and pepsin, 667.
Carpets and microbes, 524.
Cataract extraction, glaucoma following, 407; extraction of incipient, 712; extraction, prolapse of the iris in, 404; extraction, syringing out of cortical matter in, 404; extraction, variableness of astigmatism from, 740; natural course of, 294; lamellar and senile, treatment of, 209.
Catarrh of the upper air-tract, general *versus* local treatment of, 359.
Catheter, a safe female, 585.
Catlin, A. W., oxygen as a distinct remedy for disease, and a life-saving agent in extreme cases, 236.
Cattle disease in Russia, 700.
Cauda equina, operation for tumor pressing upon the, 435.
Cerebellum, new theory of the functions of, 602; tumor of, trephining for, 372.
Cerebral surgery, present state of, 668.
Chancre, hard, of the lip, and soft, of the genitals, 728; of the gum, 511; syphilitic, excision of, 501.
Chancres, genital, in woman, 362.
Chancroids, treatment of, 54.
Charaka-Samhita, a Hindu medical treatise, 543.
Cheesman, Hobart, remarks concerning stricture of the urethra in the male, 264.
Cheney, Frederick E., a case of retraction of the eyeball, 570.
Child, dry gangrene in a young, 396; gonorrhœal rheumatism in a, 279; new-born, occlusion of the duodenum in a, 453; thyrotomy in a young, 357.
Childhood, narrow prepuce and preputial adhesions in, 136.
Children, æsthetic dress a factor in discomfort and disease of, 542; in schools, scientific observation and study of, 281; peritonitis in, 580; scurvy in, 433; toilet powder for, 24; tuberculosis of, value of polyadenitis in the diagnosis of, 657; typhoid fever in, 584.
Chinn, Joseph Graves, death of, 307.
Chisholm, Julian J., an illustration of how atropia acts when applied to the cornea, 537.
Chloralamid in surgery, 55.
Chloranæmia, another view of, 661.
Chloride of gold "cure" for drunkenness, collapse of the, 604, 613.
Chloroform, death from, 692; use of, in labor, 577.
Chlorosis, treatment of, 255.
Cholecystotomy and cholelithotrity, 461; cholecystotomy, with special reference to the treatment of calculi lodging in the common duct, 645.
Cholera and the comma bacillus, 280; infantum, to check vomiting in, 347; progress of, 131; spread from Mecca, 272; transmission of, from one country to another, 280.
Chorea, early recognition and arrest of, in school children, 281; iodide of potassium for, 552.
Chyluria, thymol in, 255.
Cigarette fiend, another, 572.
Cigarettes, 764; law against, 284.
Circulation, action of cocaine on the, 182.
Clavicle, fracture of, from coughing, 651.
Cleanliness, danger of too much, 160.
Cleveland, E. S., Wocher's method of reducing subcoracoid dislocation of the humerus, 347.
Climates, American, and their physical effects, 694.
Club-foot, congenital, with absence of great toe and contiguous bones of the instep, 364; double, with club-hand, 364; open incision for, 386, 517.
Cocaine, a danger in the use of, 492, 741; action of, in the circulation, 182; death from, 545, 642; use of, 616.
Codeine, use of, 723.
Coe, H. C., uterine hemorrhage of obscure origin, 94, 108.
Coffee-drinkers in Europe, 283.
Coggswell, William, death of, 214.
Colic not necessarily a symptom in gall-stones, 466.
College of Physicians of Philadelphia, trouble in the, 19.
Colles's fracture, reduction of, under anæsthesia, 137.
Collins, Joseph, notes on some recent methods of staining for the nervous system, 449.
Coloboma of the iris, 404.
Colorado, hip disease in, 433.
Color-blindness, practical bearings of, 135.
Colored female physician, the first, 488, 587.
Colotomy, inguinal, fifty cases of, 641.
Columbian exposition, medical bureau of, 213.
Common sense in medicine, 524.
Compressed air in conjunction with medicinal solutions in the treatment of nervous and mental affections, 225.
Compressed medicines, 748.
Concussion, from explosion of torpedoes under ships, injuries caused by, 595.
Congress for the study of tuberculosis, 217, 277, 315.
Congress of American Physicians and Surgeons, 349, 369, 397, 747; and the American Association of Obstetricians and Gynecologists, 661.
Congress of German Naturalists and Physicians, 515.
Conjunctivitis, diphtheritic, treated by continuous antiseptic irrigation, 451; gonorrhœal, vaseline in, 405; granular, etiology and treatment of, 610.
Conjunctivitis, purulent, eye-drain and irrigator for use in, 755.
Connecticut, medical practice in, 390.
Conservatism, 531.
Constantinople, a medical faculty at, 545.
Constipation a neurosis, 75.
Consumptives, handkerchiefs for, 769.
Contagious disease, need of more hospitals for, 749; weekly statement, 28, 56, 84, 112, 140, 167, 196, 284, 348, 468, 495, 524, 555, 614, 644, 672, 700, 728, 756.
Contractions of the fingers and toes, 165.
Convict leases and prison management, 478.
Cornea, how atropine acts when applied to the, 537; transplantation of the, 576.
Corning, J. Leonard, the use of compressed air in conjunction with medicinal solutions in the treatment of nervous and mental affections, 225.
Corns, to remove, 255.
Coroner system in New York, 663; improvements in the, 45.
Corrosive sublimate, hot solutions of, 23; indictment of, as a disinfectant, 16.

Corson, Eugene R., some clinical jottings on twenty cases of puerperal eclampsia, 502.
Coryza, acute, treatment of, 24, 55, 138, 552, 671, 726.
Cotton reservoir, an economical, 84.
Cough, naregania in, 24.
Cow, infectious udder diseases of, in relation to epidemic diseases in man, 341.
Crandall, R. Percy, clinical notes on five cases of beri-beri, 452.
Craniectomy, linear, for defective development, 63, 455.
Creasote vapor, inhalation of, in the treatment of phthisis, 217.
Cremation in Japan, 348, 769.
Cretinism in France, 515.
Crosby, Dixi, an improved needle-holder, 166.
Crothers, T. D., the chloride of gold cure for inebriety, 613.
Croton water, contamination of, 244.
Croup, catarrhal, as one of the manifestations of lymphatism, 733; etherization in, 54, 435; vinegar vapor in, 54.
Crusade, need of a new, 272.
Cuban Medical Congress, 572, 635.
Culex pipiens, 184.
Curtis, B. Farquhar, laparotomy for acute intussusception, 534.
Cyanide of potassium, poisoning by, 687.
Cystitis, salicylic acid in the treatment of, 383.
Cystoscopy, 684.

D

Dana, Charles L., in the diagnosis of intracranial hemorrhage and acute softening, 91–106.
Dandruff, persistent, treatment of, 23.
Daniel, Z. T., removal of a lipoma tuberosum from a female Sioux, 537.
Davis, A. E., contagious diseases of the eye, some statistics with remarks, 29.
Dawbarn, Robert H. M., exsection of intestine, 698; the Hagedorn needle, 466; the right angle continuous suture, 81; water as a local anæsthetic—its discovery American and not German, 613.
Dead, disposal of the, 343.
Death, sudden, in London, 314.
Decision, an important, 763.
Delavan, D. Bryson, a new method for the administration of the iodide of potassium, 650.
Dementia, terminal, knee-jerk in, 386.
Dentistry and syphilis, 511.
Dermatitis from the use of resorcin, 715; hæmostatica, 356.
Dermatol, use of, in surgical practice, 475, 517.
Diabetes, etiology of, 539; mellitus gravidarum, 411.
Diagnosis, errors in, 616.
Diaphragm, possible case of rupture of, 581.
Diarrhœa, chronic, climatic treatment of, 419; in infants, salol in, 601; prescription for, 552, 553.
Digestion, study of, after gastrostomy, 642.
Diphtheria, 339; an early method of diagnosis, 673; at high altitudes, 419; cyanide of mercury for, 755; germ theory of, from the therapeutic point of view, 714; hydrochloric acid in, 392; local remedies for, 718; paraffin in, 755; pine-apple juice in, 55; quinine and sulphur powder for, 347; submembranous treatment of, 387.
Diphtheritic conjunctivitis treated by continuous antiseptic irrigation, 451.
Dipteræ, larvæ of, in the human intestine, 581.
Disease, changes in, 192; the unity of, 9; of animals, 694.
Disinfection of the hands, 665; of the living body, 344
Dislocation of the costal cartilages by direct violence, 211.
Dislocation, reduction of, by manipulation, 640.
Dispensary abuse, 493, 661, 692.
Diuretine, 24, 298; in genito-urinary surgery, 384.
Dock, George, the amœba coli in dysentery and liver abscess, with a new case, 7.
Doctor, the, in modern society, 660.
Doctors, do they disagree? 688; young, should they write? 213.
Dog, spontaneous tuberculosis in the, 277.
Dog's serum in tuberculosis, 217.
Donaldson, Frank, Sr., death of, 747.
Donovan's solution in gleet, 255.
Douglas, O. B., the upper air-passages and their diseases, 709.
Douglas's cul-de-sac, dropsical distention of, 50.
Dounan, William, death of, 75.
Drainage, in abdominal surgery, 77, 267; of cities and its relation to public health, 39.
Drake, G. W., nerve-force or neuricity (?), 166.
Drift, the, 273.
Drink question, London doctors on the, 391.
Drinkers, confirmed, guardians for, 274.
Drinks, the proper temperature of, 533.
Dropsy, renal, dynamic theory of, 611.
Drowning, resuscitation after, 208.
Druggist, verdict against a, 691.
Drugs, adulteration of, 437; explosion of, 556; to obtain quick action of, 24.
Drunkenness, collapse of the gold "cure" for, 604; the chloride of gold cure for, 613; praise of, 741; the sin of, 72.
Drzewiecki, Joseph, the influence of maternal impressions upon the fœtus, 529.
DuBois, Abram, obituary of, 276.
Duncan, Mathews, memorial to, 131.
Dunham, G. D., death of, 690.
Duodenum, occlusion of, in a new-born child, 453; stricture of the, 484.
Dust, inhalation of, and pulmonary disease, 723.
Dynamiter, brain of an insane, 748.
Dysentery, persulphate of iron in, 348; the amœba coli in, 7; treatment of, 709; ulcerative catarrhal, 388.
Dysmenorrhœa, treatment of, by apiol, 183.
Dyspepsia, flatulent, treatment of, 138, 552; sauerkraut in, 752.

E

Ear, gunshot wound in each, 571; healing of old perforations of the drum membrane, 368; hemorrhage in paracentesis tympani, 303; mastoid inflammation, 367.
Earache, relief of, 23.
Ear disease, thermometry in diagnostic relation to, 211.
Eastern Fever Hospital scandal in London, 315.
Ears, treatment for outstanding, 728.
Echinococcus cyst of the liver, 696.
Eclampsia, calomel in, 715; puerperal, 250, 584; puerperal, diagnosis and treatment of, 685; puerperal, pathology and treatment of, 485; puerperal, twenty cases of, 502.
Eczema, ointment for, 347; rheumatism and gout as factors in the causation of, 609; treatment of, 138.
Edebohls, George M., on combined laparotomy and gynecological operating table, 598.
Education, medical, a new scheme for a four-years' course, 512; medical, from the student's point of view, 698; preparatory, the essential, the liberal, and the technical, 336.
Edwards, Joseph F., floating hospitals for surgical operations, 165.
Egg albumin, nutritive value of rectal injections of, 14.
Eggleston, J. B., death of, 307.
Ehrlich's test in typhoid fever, 388, 521.
Einhorn, Max, methyl-blue in acute gonorrhœa, 643.
Elbow-joint, treatment of fractures involving the, 400.
Electric fan in the reduction of high temperature, 394.
Electric lights, a curious impressionability to, 608.
Electrical executions, 44, 458, 717.
Electrolysis for uterine fibromata in England, 410.
Electro-magnet, use of, for extracting buried particles of iron or steel from the tissues, 738.
Electro-microscope slide, 283.
Ellis, R., a soap-eater, 536.
Emmet's operation for laceration of the perineum, 460.
Emphysema, subcutaneous, following broncho-pneumonia, 435; acute and chronic, surgical treatment of, 379.
Endometritis, treatment of chronic, 539.
Enema, the best nutritive, 183.
Enuresis, in mouth breathers, 396; instrumental treatment of, 303; thuya in, 347; whipping for, 130.
Ephedra for rheumatism, 715.
Epididymitis, dry poultice in the treatment of, 425.
Epiglottis, troublesome symptoms caused by enlargement of the, 358.
Epilation, 413.
Epilepsy, borax in, 255; Jacksonian, trephining and excision of the cortex for, 372; medical and surgical treatment of, 637; otitic, 368; rise of temperature in the attack, 303.
Epileptic children, care of, 346.
Epileptic insanity, 135.
Epileptics, dangers to which they are exposed, 81.
Epithelioma of the perineum, electricity in the treatment of, 253.
Erysipelas, alcohol in, 24; treatment of, 255.
Erythema and nævus nuchæ, 414; multiforme, 356.
Ether, death under, 337; how to administer, 665; mode of death from, 467.
Ether-drinking in Ireland, 168.
Etherization in laryngeal croup, 435.
Ethmoid cells, various forms of disease of the, 378.
Ethmoiditis, necrosial, 309.
Etiquette, medical, 514.
Eugenol, 714.
Euphorine, 216.
Europe, medical students in, 395.
Europhen, 601.
Evans, Thomas R., fever and quinine, 196.
Exalgine, employment of, in infants, 484.
Executions, electrical, 458, 717.
Exophthalmic goitre and myxœdema, 604.
Exophthalmos, pulsating, 405.
Exostosis of the frontal and parietal bones, 162.
Extra-uterine pregnancy. *See* Pregnancy, extra-uterine.
Eye, conservative surgery of the, 491; foreign bodies in the, 406; instruments, 139; normal reflection of the, 682; some statistics of contagious diseases of the, 29; treatment of trachoma by grattage, 463.
Eyeball, retraction of the, 570.
Eyeball, ruptured, enucleation of a, 552.
Eye-drain and irrigator for use in purulent conjunctivitis, 755.
Eyelid, inwer, restoration of the, 405; upper, neuroma of the right, 405.
Eye-strain from wearing cylindrical lenses, 406; headache depending upon, 59; hyperemesis due to, 509
Eye-symptoms as a diagnostic aid to other diseases, 739.
Eyer, Alvin, injury to the thoracic duct, with an unique and inevitable death by inanition, 122.

F

Fasts, long, in India, 769.
"Fatal patient," story of the, 104, 159.
Faught, G. W., dentistry and syphilis, 511.
Favus, cats and the prophylaxis of, 466.
Feet, tender, remedy for, 138.

Fellowships, medical, 438.
Felton, George H., the physiological relation of alcohol to food, 726.
Female doctor, the first colored, 440.
Femur, treatment of simple fracture of the shaft of the, 352.
Fenwick, K. N., maternal impressions, 494.
Ferguson, John, the knee-jerk, 654.
Fever and quinine, 196; an unnamed, of the South, 82, 196; influence of one, upon another, 588; pretuberculous bacillary, 279; shamming, 743
Fibroid processes, pathology and etiology of, 397.
Fibroma, diffuse, of both breasts, 400; of the uterus, growth of, after the menopause, 667; of the uterus, Hegar's extra-peritoneal treatment of the pedicle after supra-vaginal hysterectomy for, 441.
Field, Hume, death of, 214.
Finland, a leper colony in, 543.
Fischer, Louis, an early method of diagnosis in diphtheria, 673; Professor Leyden, of Berlin, 467.
Fistulæ, fecal, following laparotomy, 583.
Flint, Austin, an abuse of postal privileges, 613.
Flogging, Siberian penal, medical notes on a case of, 495.
Florence, impure water in, 468.
Fœtus, determination of the sex of the, 103; influence of maternal impressions upon the, 42. *See* Maternal impressions.
Fog in relation to health, 281.
Food, the physiological relation of alcohol to, 768.
Foote, Charles J., the detection of the bacillus typhosus in water, 506.
Foreign body (silver dollar) in the œsophagus, 511; in the bronchus, bronchotomy through the chest-walls for, 403; in the eye, 406; in the trachea, 357.
Forest, W. E., experiments illustrating the influence of internal baths in the treatment of typhoid fever, 327.
Foundlings, mortality of, 271.
Fowls, tuberculosis of, 217.
Fox, Lorenzo S., death of, 20.
Fractures, compound, involving joints, sublimate baths in, 612; of the leg, method of applying plaster-of-Paris bandage to, 222; of the femur, some clinical features of, 734; spontaneous, 310; ununited, 15.
Freeland, J. T., œsophagotomy for the removal of a silver dollar, 511.
Friedreich's disease, relation of, to conducting paths in the cord, 409.
Frogs, attempts at skin-grafting from, 576.
Fruit-eating and gout, 160.
Fuchsine in diseases of the throat, 569.
Furunculosis, treatment of, 601.

G

Gall-stones, colic not a necessary symptom in, 302, 466; frequency of, 714; lodged in the common duct, treatment of, 645; sweet-oil for, 513, 630, 658; treatment of, 636.
Gangrene, alcohol in, 23; dry, in a child fourteen months old, 396; senile, 300; senile, treatment of, 588; symmetrical, 113.
Garbage, disposal of, 694.
Gasser, Herman, how to preserve the perineum, 752.
Gasserian ganglia, removal of the, 707.
Gastric fistula, new method of establishing a, 685.
Gastro-enterostomy, 311.
Gastrostomy for stricture of the œsophagus, 88, 517, 549; in cancer of the œsophagus, 435; new method of, 685.
Gavage in vomiting of infants, 433.
Georgia law against intemperance among medical men, 521, 546, 605.

Hemianopsia, homonymous, 13.
Hemiplegia, infantile spastic, 464.
Hemmeter, John C., crystalline forms occurring in Koch's tuberculin, 150; on the effects of certain drugs on the velocity of the blood-current, 292.
Hemorrhage, intra-cranial, and acute softening, diagnosis of, 91, 106; post-partum, caffeine in, 55; post-partum, turpentine in, 510; uterine, of obscure origin, 94, 108.
Hemorrhoids, thuya in, 255.
Hereditary transmissions, interchangeability of, 623.
Heredity, and environment, 581; influence of, in producing disease, 161.
Hernia, bilobed umbilical, 239; abdominal section for, 310; femoral and ventral, in the female, 461; inguinal, flap-splitting operation for the radical cure of, 620; radical treatment of, 310; scoliosis associated with, 584; simulating abscess, 164; ventral, prevention of, after abdominal section, 326.
Herpes, abortive treatment of, 24, 521.
Herr, F. C., maternal impressions, 659.
Heterophoria, 405.
Hiccough, arrest of, 24; lavage of the stomach for, 740.
Higgins, F. W., a case of poisoning by cyanide of potassium, with recovery, 687.
Hindu medical treatise, 543.
Hip, congenital dislocation of the, 429.
Hip disease, early resection *vs.* conservative treatment in, 136; rest in the treatment of, 491.
Hip-joint amputation, 450; amputation, control of hemorrhage during, 139; amputation of, the first, in America, 81, 492.
Hirsuties, treatment of, 347.
Hodges, R. C., a new forceps for adenoid growths, 166.
Hodgkin's disease, or simple adenia, 455.
Hoffman, Andrew B., death of, 20.
Holmes, Oliver Wendell, M.D., 242.
Hospital administration, extravagant, 336; and dispensary quarrels, 456; floating, for surgical operations, 165; reports, 389.
Hot water in surgery, 311.
Humerus, subcoracoid dislocation of, 347.
Huse, Ralph Cross, a splint for fixation of the shoulder, 755.
Husted, Nathaniel C., death of, 663.
Hutton, T. J., the weak left kidney, 659.
Hydrastis canadensis, 14.
Hydrochloric acid in diphtheria, 392.
Hydronephrosis, relation of floating kidney to, 220.
Hydrocele, pathogeny of congenital, 715; thuya in, 255.
Hygiene, Congress of. *See* International Congress of Hygiene and Demography; growth of interest in, 132.
Hyperemesis due to eye-strain or to reflex neuroses from the male genital organs, 509.
Hypertrophy, congenital, of the arm and hand, 678.
Hypnotic action of hot compresses, 23.
Hypnotism, Congress on, 187; in surgery, 286.
Hypnotizations, evils of public, 99.

Hysterectomy, abdominal, technique of vaginal fixation of the stump in, 375; early, 462; formation and final condition of the pedicle in, 666; supra-vaginal, Hegar's extra peritoneal treatment of the pedicle after, 441.
Hysteria and nasal polypus, 630; in men, 555.
Hysterical anæsthesia, pathology of, 372.

I

Identity, personal, determined by scar and other body-marks, 204.
Idiots, deformity of the palate in, 408; eye-symptoms in the Mongolian type of, 406.
Illinois Army and Navy Medical Association, 337, 488, 556.
Immigrants, the character of, 329.
Immunity, 193, 339, 345; mechanism of, 484; methods of securing, 454.
Indiana State Insane Asylum, abuses in, 515.
Indiana State Medical Society, 161.
India, female medical students in, 243; obstetric operations in, 254.
Inebriety and medical practice, 650; disease theory of, 540; treatment of paroxysmal, 713.
Infancy, diseases of, and arrested development as causes of insanity, 582.
Infant, a gigantic, 636; prolapse of the bladder in an, 631.
Infantile convulsions, frequency of, 605.
Infantile mortality, cause and prevention of, 693.
Infants, employment of exalgine in, 484; influence upon, of medicaments administered to the nursing mother, 616; tuberculosis in, 513.
Infection of wounds, conditions underlying, 349.
Infectious diseases, origin and nature of, 751; to prevent the spread of, 111.
Inflammation, chronic, diet and exercise in the treatment of, 757; nature of the process of, 697.
Influenza, 743; an infectious nervous fever, 670; and neuroses, 748; and tuberculosis, 218; camphor in, 755; discussion on, 417; extra-mundane origin of, 495; in Europe, 692; symptoms and patbological changes in the upper air-passages in, 415.
Injured, first aid to the, 465.
Inoculations, preventive, effected through mosquitoes, 334.
Insane asylums, admission of paying patients to the New York State, 439; of New York, overcrowding in, 716; politics in our, 101, 256; State, conference of superintendents of, 102.
Insane patients, service of legal papers upon, 124.
Insane, the blood and urine in the, 715.
Insanity and allied neuroses, propogation of, 715; and genius, 744; arrest of development and diseases of infancy as causes of, 582; bodily diseases and senility as causes of, 582; epileptic, 135; following gynecological operations, 356; following the use of a mydriatic, 406; peculiar to women, causes of, 582; syphilis and intemperance as causes of, 582.
Insect stings, aconite in, 254; sea-salt in, 55.
Instituto Italiano, 635.
Instruments, a universal aseptic joint for, 523.
Insurance case of medical interest, 222.
International Congress of Hygiene and Demography, 188, 279, 315, 339.

Pardee, Daniel, death of, 275.
Parents, influence of the age of, on the vitality of their children, 344.
Paris, letter from, 315; medico-legal institution in, 306.
Parker, Francis L., cases of cockle-bur in the larynx, 652.
Parkes, the late Dr. C. T., memorial of, 516.
Parsnips, wild, poisoning with, 495.
Parturient canal, full dilatation of the, before obstetrical or gynecological operations, 648.
Parturition, injuries of the vaginal outlet caused by, 134.
Patella, results of fractured, 691.
Patent medicines in the United States, 132.
Paton, Stewart, some points in the anatomy and physiology of the uterus, with special reference to the adenoid character of the endometrium, 760.
Peck, W. F., death of, 747.
Pelvic floor, injuries to the, and the method of repairing them, 666
Pelvic inflammation, 549; character and types of, 169; medico-legal aspect of, 665.
Pelvic lesions and heart disease, 603.
Pelvic suppuration, treatment of, 253, 462.
Pelvic surgery, complications in, and how to deal with them, 641.
Pelvic tumors and diseases, conservative treatment of, 410.
Pemphigus vegetans, 414.
Perineum, Emmet's operation for laceration of the, 460; lacerated, anatomical relations of, to the mechanics of its causation, 410; laceration of, part the shoulders play in, 667; preservation of the, 677, 752.
Peritonitis, acute, early operation in, 741; acute diffuse, 577; fatal, from necrosis of the uterus, 696; non-infective, 578.
Perityphlitis, 609; in the young, 434; simple incision for abscess in, 750.
Peroxide of hydrogen in asthma, 255; in typhoid fever, 658.
Personality, triple, 407.
Pettit, Louis C., eugérol, 714.
Pharyngeal mycosis, one form of, 232.
Phenocoll, hydrochlorate of, 183.
Phenylhydrazin test for sugar, 658.
Phenylurethran, 216.
Phillips, David, death of, 159.
Phillips, Wendell C., an economical cotton reservoir, 84.
Phlegmasia dolens, 136; non-puerperal, 127.
Phthisis, aspergillary, 99; attempts to discover specifics for, 381; changes in the kidney in, 453; conditions of the cure of, 697; cured, anatomical changes in, 465; decreasing death-rate of, 166; etiology, prevention, and cure of, 311; inoculations of vaccine-lymph in the treatment of, 62; localization of, in the upper lobes, 361; new and volatile antiseptic for the treatment of, 457; opium smoking in, 128; prevention of, 45; the sputum in, 379; surgical treatment of pulmonary cavities, 277; treatment of the night-sweats of, 182.
Physical examination in a bath, 458.
Physician, practising, duties of a, 700; struggles of a young, 745.
Piedmont region of the South, climate of, 360.
Pilocarpine, effect of, on the color of the hair, 424.
Pineo, Peter, death of, 337.
Piperazin, 15; in gouty conditions, 138.
Pistoia powder, 139.
Placenta, long retained, 570, 725; new method of removing a retained, 727; prævia, Portal's work on, 610; relation of weight of, to weight of the child, 154.
Plaster-of-Paris formulæ, 754.
Plecker, W. A., an unnamed fever of the South, 82.
Pleural effusion associated with disease of the abdomen, 751.
Pleurisy, interlobular, 14.
Pneumococcus in suppurative processes, 715.
Pneumonia, 675; abortion of, 753; caffeine in, 538; diagnosis of, 388; drug treatment of, 74; in infancy and early childhood, diagnosis of, 367; large doses of digitalis in, 14; temperature range in, 367; vocal fremitus in, 81; treatment of, 736.
Poisoning by cocaine, fatal, 545; by cyanide of potassium, 687.
Polak, Edward, death of, 700.
Police matrons, 478.
Police surgeons, New York board of, 76.
Poliomyelitis acuta adultorum, 353; anterior acuta, supplemental treatment of the paralysis of, 407.
Politics in our State insane asylums, 101, 256.
Pollitzer, S., excision of the syphilitic chancre, 501.
Polycoria, 404.
Polypus, nasal, and hysteria, 630; nasal, radical treatment of, 378; of the male urethra, 600; uterine, 252.
Pomade, an antiseptic adhesive, 552.
Pond, E. M., report of two cases of laparotomy, 686.
Pope, health of the, 244.
Population of England and Wales, 165; of France, 154.
Porcher, F. Peyre, degree of LL.D. conferred on, 75.
Posencephalus, trephining in, 372.
Porro's operation, 251.
Porter, William Henry, the physiological relation of alcohol to food, and its proper use in medicine, 469, 768.
Postal service, an abuse of, 605, 613; and the quacks, 516.
Post-partum hemorrhage, caffeine in, 55.
Pott's disease of the spine, an early diagnosis the best treatment of, 474; and pregnancy, 384; in middle and advanced life, 428; malignant disease of the vertebræ simulating, 533; mechanical treatment of old and neglected cases of, 385; operative treatment of, 427; paraplegia in, 385; prognosis of, 427; treatment of, 220, 428; wiring the vertebræ for, 55, 156, 427.
Powell, J. Z., the Georgia liquor statute, 521.
Powers, Charles A., on dermatol, a proposed substitute for iodoform—its use in surgical practice, 475, 517.
Powers, L. M., spreading disease by the clinical thermometer, 25.
Practitioner, consultant, and medical charity, 662.
Practitioners' Club of Chicago, 439.
Practitioners' Society of New York, 51, 106.
Pratt, Thomas Tart, death of, 275.
Pregnancy complicating abdominal tumors, method of procedure in, 460; diabetes mellitus of, 411; diagnosis of, spurious and doubtful, 253; extra-uterine, 78; extra-uterine, difficult diagnosis of, 723; extra-uterine, simulated by thinness of the uterine walls, 667; extra-uterine, some moot points in, 461; extra-uterine, treatment of, by morphine injections, 409; pathology of the albuminuria and eclampsia of, 197, 221; tubal, anatomy of, 239.
Pregnant women, ovariotomy in, 490.
Prepuce, narrow, in children, 136.
Prescriptions, Latin in, 573.
Preston, George J., two cases of homony mous hemianopsia, 13.
Presystolic bruit, 388.
Prettyman, J. S., the unity of disease, 9.
Pretubercular condition, the, 419.
Preventive medicine, 577; advance in, 279.
Prince, John A., a case of congenital hypertrophy of the arm and hand, 678.
Prison management, 554.
Prize, Alvarenga, for 1891, 215; for African medical exploration, 615; for essay on "latent tuberculosis," 279; Orton, 583, 606; v. Reinecker, 56; Welz, 615.
Prophet, the dying, 747.
Prostate, application for inflammation of the, 552; enlarged, and its operative relief, 525, 551; massage of the, 684; surgery of the, 425.
Prostatic sphincter, hypertrophy of, 425
Proteids of the blood, effects of bleeding and starvation upon the, 365.
Pruritus, etiology of, 497; ointment for, 24; senile, treatment of, 347, 552.
Pryor, W. R., the prevention of ventral hernia after abdominal section, 326.
Psoas abscess, some of the complications of, 668.
Puerperal eclampsia, 584; diagnosis and treatment of, 685; pathology and treatment of, 485; twenty cases of, 52.
Puerperal fever, 250; from the presence of a tapeworm in the uterus, 496.
Pulse, slow, sequel to a case of, 423.
Pure and impure, the, 496.
Purgative enema, a reliable, 333.
Purpura hæmorrhagica, 211; grave forms of, 424.
Pusey, W. A., medical education from the student's point of view, 698.
Pyelonephritis, calculus, 767.
Pyle, J. S., two new eye instruments, 139.
Pylorus, surgical treatment of stenosis of the, 557, 589.
Pyoktanin, failure of, as an antiseptic, 76.

Q

Quackery, legislation to repress, 693.
Quarantine, discussion on, 279, 282.
Quinine amaurosis, 406.

R

Rabies, 694; in Austria, 244; in Minnesota, 13; prevention of, in dogs, 281.
Race and disease, 660.
Radius, treatment of fracture of the lower end of the, 54
Rae, Walter, death of, 747.
Railway sanitation, 695.
Railway spine, 273, 491.
Rand, J. P., vocal fremitus in pneumonia, 81.
Rand, N. W., the perineum, how to preserve it, 677.
Rape, punishment for, 672.
Rattlesnake bite, a case of, 630.
Rauch, John H., resignation of, from the Illinois State Board of Health, 103.
Rectal disease, an analysis of 750 cases of, 285.
Rectal distention, relation of, to arterial depression, 425.
Rectal injections of egg albumin, nutritive value of, 14.
Recto-abdominal fistula following laparotomy treated by irrigation, 203.
Rectocele, posterior, 235.
Rectum, imperforate, 584, 668, 714.
Red Cross, International Congress of the, 132.
Reflexes, electro-physiology of, 407.
Renal colic, 755.
Reproductive organs, functions of, in American Indian women, 376.
Resection, spontaneous, of the heads of both humeri, 210.
Resorcin, dermatitis from the use of, 715; internal use of, 54; therapeutic value of, 74.
Respiration, forcible, 577; forcible, laryngeal tubes for, 433.
Rest cure, and cases to which it is applicable 721; surgical value of, 194, 436.
Retina, calibre of the vessels of, after injuries to the head, 406; detached, Schöler's operative treatment of, 404.
Reyburn, Robert, the first colored female physician, 586.
Reynolds, Safford, death of, 337.
Rheumatic spondylitis, 429.
Rheumatism, acute articular, bradycardia in, 424; and gout in the causation of eczema, 609; carbolic acid in, 552; cardiac phenomena of, 134; ephedra vulgaris for, 715; gonorrhœal, 365; microbic origin of, 514; rectal administration of sodium salicylate in, 299; theories of, 577.
Rhinitis, atrophic, etiology and treatment of, 173; chronic treatment of, 121.
Rhus poisoning, aristol for, 255; ipecac in, 55.
Rice culture, hygiene of, 695.
Rich, E. S., maternal impressions, 643.
Richfield Springs, the waters of, 419.
Riley, Henry A., recent medical jurisprudence, 477.
Ring-worm, cats, and the prophylaxis of, 466; of the scalp, 413.
River pollution, the bacteriological vs. the chemical view of, 488; self-correction of, 746.
Riviera, report of commissioner to the, 724.
Robinson, Beverley, note on the internal use of water in the treatment of typhoid fever, 11.
Rockwell, A. D., a danger in the use of cocaine, 492.
Roe, John O., the correction of angular deformities of the nose by a subcutaneous operation, 57.
Roome, S. Irving, the hank truss, 80.
Rose, A., river baths in winter, 4; some dangers to which epileptics are exposed, 81.
Roseberry, B. S., prolapse of the bladder in an infant, 631.
Roth, Joseph C., a hair-pin in the nose, 211.
Ruck, v., the treatment of chronic rhinitis, 121.
Rupp, Adolph, remarks on fracture of the sternal end of the clavicle due to muscular action, 651.
Russia, the medical profession in, 18; women apothecaries in, 556.
Ruth, M. L., death of, 747.
Ryerson, G. Sterling, thermometry in diagnostic relation to ear disease, 211.

S

Sacral section, application of, in gynecological work, 459.
Sacro-iliac junction, injuries to the, 430.
Sailors, diet of, 341.
St. Bernard, Hospice of, 587.
St. Mark's Hospital, 606.
Salol in infantile diarrhœa, 601.
Sandwich Islands, population of, 393.
Sarcoma of the dorso-scapular region, 609; of the metacarpus, with rapid generalization, 162; primary, of the broad ligament, 356; unusual case of, 357.
Satterlee, Richard H., some abnormal eye-symptoms as a diagnostic aid to other diseases, 739.
Satterthwaite, Thomas E., pulmonary carcinoma and sarcoma, 257.
Scalp-wounds, uniting the edges of, without sutures, 755.
Scanzoni, Friedrich W., death of, 48.
Scarpa, memorial to, 717.
Scarlatina, acetate of ammonium in, 24; germs, inoculation of a Japanese with, 270; prophylaxis of complications in, 367.
Schofield, C. S., offensive lochia due to laceration of the uterine and vaginal tissues, with no rise in temperature, 740.
Schöler's operative treatment of detached retina, 404.
Schools, hygiene of, 341.
Sciatica, phenacetin in, 24.
Scientists and mind-reading, 334.
Sclerosis, pathology and etiology of, 397.
Scoliosis associated with hernia, 584; in its relation to flat foot, 429; pathological anatomy of, 429; prognosis of, 220.
Scurvy, 341; in children, 433.
Seabrook, H. H., the natural course of cataract, 294.
Seibert, A., some clinical observations at the St. Francis Hospital, 298.
Semple, Robert Hunter, death of, 222.
Senility and bodily diseases as causes of insanity, 582.
Senn, N., the surgical treatment of pyloric stenosis, with a report of fifteen operations for this condition, 557, 589.
Sepsis, puerperal, one phase of, 161; the conqueror of, 242.
Serpents, venomous, treatment of bites of, 668.
Sewage, chemical treatment of, 341.
Sewall, Charles Albert, report on a case of poisoned wound by the bite of a rattlesnake (crotalus), 630.
Seward, Sara C., death of, 47.
Sex of the child, prognosing the, 664; the knee a distinction of, 603.
Shakespeare, cause of the death of, 394, 492.
Shaking, therapeutic value of, 574.
Shears, Charles H., death of, 46.
Sheppard, C. E., suicide of, 103.
Shimwell, Benjamin T., intestinal anastomosis, 652.
Ship surgeons, 100, 212, 486.
Shock and traumatism, 582.
Shoulder, resection of, prevention of a dangling limb after, 364; splint for fixation of the, 755.
Skin, tuberculosis of the, 376.
Skin-diseases associated with derangements of the nervous system, 413.
Skin-grafting, 412; by Thiersch's method, 405.
Skinner, Albert, death of, 102.
Skull, union of bones of, after trephining or compound fracture, 554.
Sligh, J. M., bilobed umbilical hernia—operation—recovery, 239; congenital malformation — atresia ani-vesicalis, with an abnormal peculiarity not heretofore described, 738.
Small pox, precautions against the introduction of, from Canada, 746; stamping out, 396.
Smart, Charles, personal identity determined by scar and other body marks, 204.
Smith, A. Alexander, clinical remarks on acute pulmonary œdema, 730, 749.
Smith, David S., death of, 747.
Smith, E. H., another side to the "maternal impressions" question, 196
Smith, Frank Fremont, radical change in application of Koch's lymph, attended by marked success—fever reactions prevented, 478.
Smith, Stephen, M.D., LL.D., 19; the art of teaching medicine, 564.
Smith, Thomas L., death of, 214.
Snake poisoning, remedy for, 214.
Snakes, vaccination against, 690.
Snare, universal double-acting, 26.
Soap-eater, a, 536
South, an unnamed fever of the, 82, 196.
Southern Surgical and Gynecological Association, 639, 665.
Specimens, museum, preparation of, 138.
Speer, James Ramsey, death of, 307.
Spina bifida with partial motor and sensory paralysis, 364.
Spinal cord, chronic fibroid processes of the, 398
Spinal nerve roots, lesions of, from secondary carcinomatous growths, 642.
Spine, malignant disease of, simulating Pott's disease, 427; surgery of the, 371; the typhoid, 428.
Splints, felt, substitute for, 23; for fixation of the shoulder, 755; internal angular arm, 138; lateral traction fixation, 365.
Spondylitis, cervical, 428; rheumatic, 429; syphilitic, in children, 384.
Spotswood, William A., death of, 306.
Sprains, treatment of, 23.
Spratling, L. W., a case of hæmatoma auris without mental disease, 631.
Spratling, William P., paranoia, a study of some of the more prominent types, with contribution of three cases, 679.
Spray-tube, a new, 56.
Squint, diverging, operative treatment of, 405.
Stanton, R. J., the first colored female physician, 586.
Staphylococcus pyogenes, simultaneous existence of two substances in cultures of, 741.
Stark, Henry S., on the character and types of pelvic inflammations in the female, 169.
State Charities Aid Association, 335.
Steamships, enforcing sanitary measures on, 335; medical officers of, 212, 486; to Southern ports, need of surgeons on, 100.
Steinthal, Martin, celebration of the medical jubilee of, 643.
Sterility in woman, 317, 458; treatment of, 253.
Stevenson, Dr., death of, 20.
Stickler, Joseph William, perfumery in hay fever, 466; the truth about tuberculin, 126.
Stomach, atrophy of the mucous glands of the, 483; condition of, in tuberculosis, 278; dilatation of the, 493; essential spasm of the cardiac orifice of the, 332; establishing a fistula of the, 685; new diagnostic sign of cancer of the, 690; physiology of the glands of the, 333; rupture of, from use of the stomach-pump, 458; statistics of exsection of, 569; surgical treatment of pyloric stenosis, 557, 589.
Stomatitis aphthosa, 434.
Stone in the bladder, undetected, 384.
Stover, David Humphreys, death of, 337.

Strabismus, non-operative treatment of, 50.
Strang, Ira D., death of, 307.
Stratton, R. T., abortion of pneumonia, 753.
Straw-ashes as a surgical dressing, 755.
Strictures, intestinal, diagnosis of innocent from malignant, 641; of the duodenum, 484; urethral, 264, 610; urethral, excision and urethroplasty for a radical cure of, 383; urethral, in the female, reflex irritations and neuroses caused by, 362; urethral, square sounds in the treatment of, 137; urethral, treatment of, 426.
Strontium, salts of, in albuminuria, 636.
Strouse, A. N., a new spray-tube, specially designed for the application of medicated oils and fats to any part of the respiratory tract, 56.
Strychnine as a heart stimulant, 619.
Stuart, T. H., death of, 186.
Sturmdorf, Arnold, symmetrical gangrene, 113.
Styracol, 55.
Sugar in the urine, modified phenylhydrazin test for, 658.
Suicide, a dramatic, in Paris, 634; attempted, by swallowing a teaspoon, 648; in Indiana, 745; in the armies of France, 769; in the Italian army, 214.
Sulfaminol, 337.
Sulphonal, dangers of, 14.
Surgeon-General of the army, report of, 716.
Surgery, amateur, 556; progressive, 666.
Suture, opossum-tail, 668; the right-angle continuous, 81.
Sweet-oil for gall-stones, 513.
Synovitis, tubercular, 51.
Syphilis and dentistry, 511; and intemperance as causes of insanity, 582; hereditary, 754; hydrargyrum formemidatum in, 357; in South Africa, 587; infection of unique case of, 302; intra-cranial, 407; late manifestations of, 369; manifestations of, in the throat, local treatment for, 206; of the brain, 521; of the lungs, 332; points on, 586; pre-Columbian, 129; pulmonary, in the adult, 247; reinfection of, 587; suspected, the diagnosis being verified by treatment, 301; treatment of, 50; why it is not aborted by the early destruction or excision of its initial lesion, 1, 107.
Syphilitic cachexia, 363; chancre, excision of the, 501; transmission, hereditary, through two generations, 363.
Syringomyelia, 704.

T

Table, combined laparotomy and gynecological operating, 598.
Tachycardia, essential paroxysmal, 701.
Talipus equino-varus, open incision for, 517; requiring operation, 137.
Tall men, where they are found, 769.
Tape-worm, cocoanut for, 55, 137; in the uterus, 496.
Taylor, John N., vaccine lymph in tuberculosis, 282.
Taylor, R. W., why syphilis is not aborted by the early destruction or excision of its initial lesion, 1, 107.
Taylor, W. H., death of, 132.
Teaching medicine, the art of, 564, 698.
Teeth, artificial, 395; bacteriology of caries of the, 280.
Temperance Congress, 101, 103.
Temperature, human, vagaries of, 689.
Tendon reflex, patellar, 386.
Tenement-house inspection by the sanitary police, 762.
Testicle, diagnosis of tuberculosis of, 279; treatment of tuberculosis of, 277.
Tetaniferous man, 284.
Tetanus, pathology and treatment of, 98.
Therapeutic hints, new department of, 17.
Therapeutics, mental, 583.
Thermometer in abdominal surgery, 609; spreading disease by the, 25.
Thermometry in diagnostic relation to ear disease, 211.
Thomas, J. D., a case of amputation at the hip-joint by Wyeth's method—death, 450.
Thomas, T. Gaillard, conservative surgery applied to the ovary, 729.
Thompson, Allen L., death of, 338.
Thomsen's disease, 354.
Thoracic duct, injury to the, followed by death by inanition, 122.
Thorax, respiratory changes of pressure within the, 366.
Throat, fuchsine in diseases of the, 569; local treatment for syphilitic manifestations of the, 206.
Thymol in chyluria, 255.
Thyrotomy in a child eighteen months of age, 357.
Tibbets, L., a remarkable case of gun-shot wound in each ear, with recovery, 571.
Tinea trichophytina cruris, epidemic of, 316.
Tin-plate treatment of ulcers of the leg, 572.
Tissues, a method of rendering transparent thick sections of, 521.
Tobacco, consumption of, in France, 615; smoking of, rendered harmless, 615; vapor of, toxic effect of, 548.
Toe-nail, ingrowing, treatment of, 55.
Tokyo Medical Association, 616.
Tonics, some new heart and nerve, 514.
Tonsils, as guard-houses, 742; in health and disease, 358.
Tooth wash, 24.
Torpedoes, injuries produced by the concussion of, beneath vessels, 595.
Torticollis, 429; congenital, with facial atrophy, 433.
Trachea, foreign body in the, 357.
Tracheotomy on a dog, 616.
Trachoma, etiology and treatment of, 610; grattage for, 463, 656; roller-forceps for pressing out granulations in, 406.
Training school for nurses, indictment of the, 744.
Transparency of thick sections, method of securing, 521.
Traumatism and shock, 582.
Trendelenburg's posture in gynecology, 461.
Trephining, indications for, 484.
Trichloracetic acid, how to apply, 754.
Truss, the hank, 80.
Trusses, to obviate chafing from, 24.
Tryon, J. Rufus, injuries caused by the concussion produced by explosion of torpedoes beneath iron-clad and other vessels of war in Mobile Bay, 1865, 595.
Tubal pregnancy, anatomy of, 239.
Tubercle bacilli, means of destroying, 279; number of, in phthisical sputum, 72; toxic and vaccinal substances contained in cultures of, 277.
Tuberculin, 516, 605; as an alterative, 381; composition of, 137; crystalline forms occurring in, 150; discussion on, 360; in Russia, 728; modifications of, 155, 219; new use for, 575; radical change in the application of, attended by marked success, 478; the lay of the lymph, 28; the truth about, 126.
Tuberculocidin, 689.
Tuberculosis, acute miliary, 126; and broncho-pneumonia, differential diagnosis of, 367; congress for the study of, 217, 277; dogs and goats not immune from, 316; dog's blood serum in, 54; etiology of, 342; frequency of the localization of, in the upper lobes of the lungs, 361; gallinaceous and human, non-identity of, 316; hereditary, 218; hereditary, influence of high altitudes upon, 420; hospital treatment of, 277; human and animal, 217; in children, value of polyadenitis in the diagnosis of, 657; in infants, 513; infection of the central nervous system, 373; inoculation with attenuated cultures, 217; Lannelongue treatment of, 128, 157; laryngo-tracheal neoplasms of, 416; nasal, 378; of bones and joints, treatment of, by parenchymatous and intra-articular injections, 371; of the lung, specimen of, showing a peculiar distribution of the lesions, 80; of the ovaries and tubes, 767 of the skin, 376; of the skin, treatment of, 411; potential factors in the spread of, 21; prophylaxis of, 278; pseudo-, 657; pulmonary, 164; pulmonary, etiology, prevention, and cure of, 311; spontaneous healing of, 632; surgical, Koch's method in, 219; treatment of, 217, 581; treatment of, by chloride of zinc, 128, 157; vaccine lymph in, 282.
Tuberculous infection, predisposition to, 452; lung, excision of the apex of a, 439
Tucker, Ervin A., how to preserve the perineum, 752.
Tuckerman, L. B., management of the paroxysmal inebriate, 713.
Tumors, retro-peritoneal, 402.
